A15 ANTIDOTES IN DEPTH

Vitamin K₁

Mary Ann Howland

Vitamin K₁ (phytonadione) is the commercial preparation of the natural form of vitamin K (phylloquinone) that is indicated for the reversal of an elevated prothrombin time (PT) or an international normalized ratio (INR) in patients with xenobiotic induced vitamin K deficiency. Acquired vitamin K deficiency typically results from the therapeutic administration of warfarin, or following the overdose of warfarin or a long-acting anticoagulant rodenticide (LAARs), such as brodifacoum. The optimal dosage regimen of vitamin K₁ to treat patients who develop an elevated INR while receiving warfarin is given in the 2012 American College of Chest Physicians consensus guidelines.¹ Oral administration of vitamin K₁ is safe and effective. Because intravenous (IV) administration of vitamin K₁ may be associated with anaphylactoid reactions, it should be avoided unless serious or life-threatening bleeding is present. Subcutaneous administration should only be considered when a patient is unable to tolerate oral vitamin K therapy and is not clinically compromised enough to necessitate IV vitamin K₁.⁸

HISTORY

It was noted in 1929 that chickens fed a poor diet developed spontaneous bleeding. In 1935, Dam and coworkers discovered that incorporating a fat soluble substance, defined as a “koagulation factor,” into the diet could correct the bleeding, leading to the name vitamin K.^{19,32,37}

PHARMACOLOGY

Chemistry

Vitamin K is an essential fat-soluble vitamin that encompasses at least two distinct natural forms. Vitamin K₁ (phytonadione, phylloquinone) is the only form synthesized by plants and algae. Vitamin K₂ (menaquinones) is actually a series of compounds with the same 2-methyl-1, 4-naphthoquinone ring structure as phylloquinone, but with a variable number (1–13) of repeating five-carbon units on the side chain. Bacteria synthesize vitamin K₂ (menaquinones). Most of the vitamin K ingested in the diet is phylloquinone (vitamin K₁).

Related Vitamin K Compounds

Vitamin K₁ (phytonadione) is the only vitamin K preparation that should be used to reverse anticoagulant induced vitamin K deficiency or to treat infants or pregnant women. In addition, patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency have an increased risk of hemolysis with other vitamin K preparations. Vitamin K₁ is superior to the other previously commercially available vitamin K preparations because it is more active, requires smaller doses, and has fewer associated risks.^{15,34}

Vitamins K₃ (menadione) and K₄ (menadiol sodium diphosphate) are no longer approved by the US Food and Drug Administration, (FDA) because they can produce hemolysis, hyperbilirubinemia, and kernicterus in neonates, as well as hemolysis in G6PD-deficient patients. The only advantage that menadione and menadiol sodium diphosphate have is that

these preparations are absorbed directly from the intestine by a passive process that does not require the presence of bile salts. Theoretically, they are advantageous for patients with cholestasis or severe pancreatic insufficiency. However, they are neither interchangeable with vitamin K₁, nor a substitute for vitamin K₁, when anticoagulants such as warfarin or a LAAR are responsible for coagulation deficits. Therefore, for a patient deficient in bile salts who requires vitamin K₁, exogenous bile salts, such as ox bile extract 300 mg or dehydrocholic acid 500 mg, should be given with each dose of oral vitamin K₁.²⁷

Mechanism of Action

Activation of coagulation factors II, VII, IX, and X, and proteins S, C and Z require γ -carboxylation of the glutamate residues in a vitamin K-dependent process. Only the reduced (K₁H₂, hydroquinone) form of vitamin K manifests biologic activity. During the carboxylation step, the active reduced vitamin K₁ is converted to an epoxide. This 2,3-epoxide is reduced and recycled to the active K₁H₂ in a process that is inhibited by warfarin (Fig. 60–2). For further details, the reader is referred to an in-depth model of the chemical basis of this reaction.^{10,42} The phytonadione form of vitamin K can be activated to the reduced, vitamin K₁H₂ form directly by nicotinamide adenine dinucleotide (phosphate) (NAD(P)H)-dehydrogenase (DT-diaphorase) enzymes that can use both NADH and NADPH in a pathway that is relatively insensitive to warfarin, while the vitamin K 2,3-epoxide form cannot be activated through this pathway.^{32,36,37,39}

Daily Requirement

The human daily requirement for vitamin K is small; the Food and Nutrition Board set the recommended daily allowance at 1 μ g/kg/d of phyloquinone for adults, although 10 times that amount is required for infants to maintain normal hemostasis.³¹ Vitamin K dependent extrahepatic enzymatic reactions relate to carboxylation of proteins in the bone, kidney, placenta, lung, pancreas, and spleen, and include the synthesis of osteocalcin, matrix Gla protein, plaque Gla protein, and one or more renal Gla proteins.^{31,32,36} Variations in dietary vitamin K intake while receiving therapeutic oral anticoagulation can result in significant over or under anticoagulation.^{1,14}

Pharmacokinetics of Dietary Vitamin K

Dietary vitamin K in the forms of phyloquinone and menaquinones is solubilized in the presence of the bile salts, free fatty acids, and monoglycerides, which enhance absorption. Vitamin K is incorporated into chylomicrons, entering the circulation through the lymphatic system in transit to the liver.³² In the plasma, vitamin K is primarily in the phyloquinone form, whereas liver stores are 90% menaquinones and 10% phyloquinone.³² Within 3 days of a low vitamin K diet, a group of surgical patients showed a fourfold decrease of liver vitamin K concentrations, without an effect on their PT.³⁵ Rats given a vitamin K deficient diet develop severe bleeding within 2 to 3 weeks.

Pharmacokinetics of Administered Vitamin K₁

There are only a limited number of pharmacokinetic studies of vitamin K₁.^{7,16,26,43} One study evaluated the pharmacokinetics of vitamin K₁ in healthy volunteers, brodifacoum anticoagulated rabbits, and a patient poisoned with brodifacoum.²⁶ In the volunteers and the poisoned patient, a 10 mg IV dose of vitamin K₁ had a half-life of 1.7 hours. After oral administration of doses of 10 and 50 mg of vitamin K₁, peak concentrations of 100 to 400 ng/mL and 200 to 2000 ng/mL, respectively, occurred at 3 to 5 hours. Bioavailability varied significantly among patients (10%–65%) for both doses and in individual patients with the 50 mg dose. Oral vitamin K₁ is absorbed in an energy dependent saturable process in the proximal small intestine, which likely contributes to the variability.²⁶ In maximally brodifacoum anticoagulated rabbits, IV vitamin K₁ (10 mg/kg) increased prothrombin complex activity from 14% to 50% by 4 hours and to 100% by 9 hours, after which it declined with a half-life of 6 hours.²⁶ Similarly, high doses of oral vitamin K₁ were effectively used to treat a patient anticoagulated with brodifacoum.⁷

The pharmacokinetics of oral and intramuscular (IM) vitamin K₁ were compared in eight healthy female volunteers. Baseline serum vitamin K₁ concentrations were 0.23 ng/mL. Following the oral administration of 5 mg of vitamin K₁ peak serum concentrations of 90 ng/mL were achieved between 4 and 6 hours. These concentrations dropped to a steady state of 3.8 ng/mL, and exhibited a half-life of about 4 hours.

The pharmacokinetics were distinctly different and quite variable after IM administration. IM administration of 5 mg of vitamin K resulted in peak serum concentrations of only 50 ng/mL, with delays from 2 to 30 hours following administration and with the maintenance of a plateau for about 30 hours.¹⁶ Consequently, IM administration is not recommended; either oral or IV administration is more appropriate, and the route will be defined by the severity of bleeding. Only in the case of

acute gastrointestinal disease in a patient without life-threatening over anticoagulation is the subcutaneous route an appropriate alternative to the oral route (Table 60–3).

Pharmacodynamics of Administered Vitamin K₁

The time necessary for the INR to return to a safe or normal range is variable and dependent on the rate of absorption of vitamin K₁, the serum concentration achieved, and the time necessary for the synthesis of activated clotting factors. A decrease in the INR can often occur within several hours, although it may take 8 to 24 hours to reach target values.^{1,6,12,23,28} Maintenance of a normal INR depends on the half-life of the vitamin K₁, maintenance of an effective serum concentration, and the half-life of the anticoagulant involved. The IV route is unpredictably faster than the oral route in restoring the INR to the chosen target range.^{1,16,21} A comparison of oral versus IV vitamin K₁ therapy for excessive anticoagulation, without major bleeding, demonstrated that individuals with INRs of 6 to 10 had similarly improved INRs at 24 hours.²¹ The onset of action began at 2 hours with IV compared to 6 hours with oral.²¹ The IV group was more often overcorrected to an INR of less than two.²¹ In a randomized controlled trial in asymptomatic patients on warfarin with an INR between 4.5 and 10, the administration of 1 mg of vitamin K orally was associated with a faster return to a therapeutic INR than with 1 mg administered subcutaneously.⁸

Vitamin K Deficiency and Monitoring

Vitamin K deficiency can result from inadequate intake, malabsorption, or interference with the vitamin K cycle. Malnourishment and any condition in which bile salts or fatty acids are inadequate, such as extrahepatic cholestasis or severe pancreatic insufficiency, can lead to vitamin K deficiency. Additionally, multifactorial etiologies place newborns at risk for hemorrhage. Phylloquinone does not readily cross the placenta, and breast milk contains less phylloquinone than vitamin K fortified formula. Fetal hepatic stores of phylloquinone are low, and treatments such as maternal anticonvulsant therapy may lead to increased vitamin K metabolism.^{32,36} Although menaquinones are produced in the colon by bacteria, it is unlikely that enteric production contributes significantly to vitamin K stores or that eradication of the bacteria with antibiotics, without a coexistent dietary deficiency of vitamin K, results in deficiency.³² Determination of vitamin K deficiency is usually established on the basis of a prolonged PT or INR, which are surrogate markers of specific coagulation factors. Measurement of the vitamin K dependent factors, II, VII, IX, and X, appears to be an effective way to determine the adequacy of vitamin K₁ dosing.¹⁷ Serial measurements of factor VII, the factor with the shortest half-life, allow for the early detection of inadequate vitamin K in the diet or a therapeutic regimen.⁷ Direct measurement of serum vitamin K concentrations is done by high-performance liquid chromatography analysis. The human serum vitamin K concentration required for adequate production of activated clotting factors in the presence of LAARs is still unclear. A single study in a patient who overdosed on brodifacoum suggested that a serum vitamin K concentration of 0.2 to 0.4 µg/mL was sufficient to achieve a normal coagulation profile. Prior studies suggested 1.0 µg/mL was necessary in rabbits.^{7,26}

ROLE IN XENOBIOTIC INDUCED VITAMIN K DEFICIENCY

Oral anticoagulants are vitamin K antagonists that interfere with the vitamin K cycle, causing the accumulation of vitamin K 2,3-epoxide, an inactive metabolite. Warfarin is a strong irreversible inhibitor of the vitamin K 2,3 epoxide reductase, which regenerates vitamin K into its active (K₁H₂, hydroquinone) form.³ The superwarfarins are even more potent vitamin K reductase inhibitors. Without exogenous interference, vitamin K is recycled and only 1 µg/kg/d is required in adults to maintain adequate coagulation. DT-diaphorases are warfarin insensitive enzymes capable of reducing vitamin K₁ to its active hydroquinone form, but they are incapable of regenerating vitamin K from vitamin K 2,3-epoxide following carboxylation of the coagulation factor (Fig. 60–2).³ Thus, in the presence of warfarin or superwarfarin, additional vitamin K₁ must be administered to supply this active cofactor for each and every carboxylation step, because it can no longer be recycled.⁷ The minimum vitamin K₁ requirement in the presence of a LAAR is unknown. Other compounds have varying degrees of vitamin K antagonistic activity and include the N-methyl-thiotetrazole side-chaincontaining antibiotics such as moxalactam and cefamandole (Chap. 57), as well as salicylates (Chap. 39).³²

ADVERSE EFFECTS AND SAFETY ISSUES

Although vitamin K₁ can be administered orally, subcutaneously, intramuscularly, or intravenously, the oral route is preferred for maintenance therapy. When administered orally, vitamin K₁ is virtually free of adverse effects, except for overcorrection of the INR for a patient requiring maintenance anticoagulation. The preparations available for IV administration are rarely associated with anaphylactoid reactions. Because of the lipid solubility of vitamin K, these

preparations are not available in solution but rather as an aqueous colloidal suspension of a polyoxyethylated castor oil derivative, dextrose, and benzyl alcohol. IV administration has resulted in death secondary to anaphylactoid reactions, probably as a result of the colloidal formulation of the preparation.^{4,9,22} Numerous anaphylactoid reactions are reported, even when the preparation is properly diluted and administered slowly.^{13,25,29,41} In a 5 year retrospective study, two patients experienced “clinical anaphylaxis” shortly after initiation of 0.5 to 1 mg IV vitamin K₁ diluted in 50 mL D₅W to be infused over one hour. Based on the total number of 6572 administered doses of vitamin K₁ infused according to this protocol, the estimated incidence of “clinical anaphylaxis” was 3 in 10,000. Rarely, subcutaneous and IM routes of administration may also result in an anaphylactoid reaction.¹³ Liposomal preparations, which may become safer alternatives, are in development.

PREGNANCY AND LACTATION

Vitamin K₁ is listed as FDA pregnancy category C. There are no reproductive studies in animals. However, Briggs⁵ suggests that vitamin K is compatible with human pregnancy and is the treatment of choice for vitamin K deficiency during pregnancy and to prevent hemorrhagic disease in the newborn. Briggs also states that vitamin K is compatible with breastfeeding. However, the amount of vitamin K transferred in mother’s milk is not usually enough to prevent hemorrhagic disease in the newborn without supplementing the newborn directly.

DOSING AND ADMINISTRATION

The optimal regimen for vitamin K₁ remains unclear. Variables include the vitamin K₁ pharmacokinetics and the amount and type of anticoagulant ingested.³⁰ Reported cases of LAAR poisoning have required as much as 50 to 250 mg of vitamin K₁ daily for weeks to months.^{2,7,11,18,20,33,40} A reasonable starting approach for a patient who has overdosed on LAAR is 25 to 50 mg of vitamin K₁ orally three to four times a day for 1 to 2 days. For usually large oral vitamin K doses the IV formulation can be given orally.⁸ The INR should be monitored, and the vitamin K₁ dose adjusted accordingly. Once the INR is less than 2, a downward titration in the dose of vitamin K₁ can be made on the basis of factor VII analysis. For an ingestion of brodifacoum, serial serum concentrations of brodifacoum may be helpful in determining the ultimate duration of treatment.^{7,24}

The management of patients with elevated INRs secondary to excessive warfarin is described in [Table 60–2](#). IV administration of vitamin K₁ should be reserved for life threatening bleeding and serious bleeding at any elevation of INR.¹ Under these circumstances, patients may be supplemented with prothrombin complex concentrate and fresh frozen plasma (FFP), based on a risk-to-benefit analysis. A starting dose of 10 mg of vitamin K₁ is recommended. To minimize the risk of an anaphylactoid reaction, the preparation should be diluted with preservative-free 5% dextrose, 0.9% sodium chloride, or 5% dextrose in 0.9% sodium chloride, and administered slowly, using an infusion pump, over a minimum of 20 minutes according to the 2012 American College of Chest Physicians guidelines.¹ The package insert recommends administration at a rate not to exceed 1 mg/min in adults.³⁸ Precautions should be anticipated in the event of an anaphylactoid reaction.

Because the duration of action of vitamin K₁ is short-lived, the dose must be repeated two to four times daily. The onset of the effect of vitamin K₁ is not immediate, regardless of the route of administration.

FORMULATION AND ACQUISITION

Vitamin K₁ is available for IV and subcutaneous administration as phytonadione injection emulsion in 2 mg/mL and 10 mg/mL concentrations. These preparations contain benzyl alcohol (0.9%) as a preservative. Oral vitamin K₁ is available as Mephyton in 5 mg tablets.

SUMMARY

- Vitamin K₁ (phytonadione) is indicated for the reversal of an elevated PT or INR in patients with xenobiotic induced vitamin K deficiency.
- IV administration is reserved for patients with serious or life-threatening bleeding. The intravenous route is rarely associated with consequential adverse reactions.
- Vitamin K₁ is administered with other therapies such as prothrombin complex and FFP that have rapid onsets of action.

- The onset of action of vitamin K₁ is delayed for several hours regardless of the route of administration.

A16 ANTIDOTES IN DEPTH

Protamine

Mary Ann Howland

Protamine is a rapidly acting antidote that is used primarily to reverse the anticoagulant effects of unfractionated heparin (UFH). It neutralizes the anti-IIa activity of low-molecular-weight heparin (LMWH) and incompletely neutralizes the anti-Xa activity of LMWH, which may normalize activated partial thromboplastin time (aPTT) and the thrombin time, but variably resolves clinical bleeding. Protamine has no effect on heparin pentasaccharide fragments or analogs such as fondaparinux.

HISTORY

The antidotal properties of protamine were recognized in the late 1930s, leading to its approval as an antidote for heparin overdose in 1968.⁶⁹ However, the largest body of literature pertaining to protamine originates from its use in neutralizing heparin following cardiopulmonary bypass and dialysis procedures.

PHARMACOLOGY

Chemistry

The protamines are a group of simple basic cationic proteins found in fish sperm that bind to heparin to form a stable neutral salt, rapidly inactivating heparin and reversing its anticoagulant effects.⁷⁶ Commercially available protamine sulfate is derived from the sperm of mature testes of salmon and related species. Upon hydrolysis, protamine yields basic amino acids, particularly arginine, proline, serine, and valine, but not tyrosine and tryptophan.

Related Protamine Variants

In animal studies, synthetic protamine variants, not available for clinical use, were effective in reversing the anticoagulant effects of LMWH and are reported to be less toxic than protamine.^{11,41,85,86} The effects of protamine sulfate and protamine chloride appear to be comparable.⁵³

Mechanism of Action

Heparins are large electronegative xenobiotics that are rapidly complexed by the electropositive protamine, forming an inactive salt. Heparin is an indirect anticoagulant, requiring a cofactor. This cofactor, AT, was formerly called antithrombin III. Heparin alters the stereochemistry of AT, thereby catalyzing the subsequent inactivation of thrombin and other clotting factors.³² Only about one-third of an administered dose of unfractionated heparin binds to AT, and this fraction is responsible for most of its anticoagulant effect.^{3,55} LMWH has a reduced ability to inactivate thrombin as a result of lesser AT binding, but the smaller fragments of LMWH inactivate factor Xa almost as well as the larger molecules of UFH, allowing for equivalent efficacy. Immuno-electrophoretic studies demonstrate that because of the net positive charge of protamine, it has a greater affinity for heparin than heparin for AT, producing a dissociation of the heparin-AT complex and favoring a protamine-heparin complex.⁷³ This complex is removed by the reticuloendothelial system.²

PHARMACOKINETICS AND PHARMACODYNAMICS

Normal volunteers, free of cardiovascular disease and heparin-free, received 0.5 mg/kg protamine intravenously over 10 min. In this study, the protamine plasma half-life was 7.4 minutes, and it was undetectable within 20 minutes.

Pharmacokinetic modeling did not fit a typical pattern.⁸ The same investigators administered 250 mg of protamine intravenously over 5 minutes at the end of cardiopulmonary bypass for heparin reversal revealing a total protamine half-life

(free plus bound to heparin) of 4.5 minutes and this study, a two-compartment model best explained the data.

ROLE IN REVERSING HEPARINS

Protamine is indicated to reverse anticoagulant effects of heparin.²⁸ It is commonly used during coronary artery bypass graft (CABG) and cardiac valve surgeries, abdominal aortic aneurysm and other open abdominal surgeries, in fistula placement and noncardiac vascular surgeries, during catheterization for cardiac or electrophysiologic procedures, and in hemodialysis.^{9,37,61,92} Multiple controlled human trials substantiate the effectiveness of protamine in terminating the effects of heparin.^{33,37,92} Protamine can be used in heparin overdose.

ROLE IN REVERSING LOW-MOLECULAR-WEIGHT HEPARIN

In contrast to the case of heparin, there is no proven method for completely neutralizing LMWH. Protamine neutralizes the anti-IIa activity of LMWH and a variable portion of the anti-Xa activity of LMWH.²⁸ Because the interaction of protamine and heparin is dependent on the MW of heparin, LMWH (mean MW, 4500 Da) has reduced protamine binding. The protamine resistant fraction in LMWH is an ultra-low-molecular-weight fraction with low sulfide charge.²¹ No human studies offer convincing evidence either demonstrating or disputing a beneficial effect of protamine as treatment for hemorrhage following LMWH use.²⁸ Case studies and case reviews report both success and failure of protamine administration to reverse LMWH-associated bleeding.^{5,10,11,16,41,62,64,84–86,95}

ADVERSE EFFECTS AND SAFETY ISSUES

Protamine is routinely used in the neutralization of heparin at the completion of CABG surgery. More than a million coronary revascularizations are performed each year in the United States. However, unlike previous years, only one-fourth of those cases are now CABGs and routinely expose patients to protamine. Since the advent of CABG surgery, there have been approximately 100 deaths reported in total with the use of protamine in these circumstances. It is largely in this setting that the adverse effects of protamine are also documented and studied.^{38,39,59,72} It is often difficult to separate the adverse effects caused by protamine from those of the protamine–heparin complex or those actually related to heparin. Adverse effects associated with protamine include both administration rate- and non-rate-related hypotension,^{18,24–26,29,31,43,46,79,81} anaphylaxis,^{42,58} anaphylactoid reactions,^{45,65,67} bradycardia,¹ thrombocytopenia,⁹⁰ thrombogenicity,²⁰ leukopenia, decreased oxygen consumption,^{87,89} acute respiratory distress syndrome (ARDS),^{7,83} pulmonary hypertension and pulmonary vasoconstriction,^{13,35} cardiovascular collapse,^{56,77} and dose dependent paradoxical anticoagulation with protamine excess.^{2,6,47,70,71}

Mechanisms for these adverse effects are multifactorial. Some contribution may result from significant electropositivity of protamine. The protamine–heparin complex activates the arachidonic acid pathway, and the production of thromboxane A₂ is at least partly responsible for some of the hemodynamic changes, including pulmonary hypertension.^{13,19,36,66,91}

Pretreatment with indomethacin limits these effects.^{19,36,66,91} Free protamine or protamine complexed with heparin can convert L-arginine to nitric oxide (formerly called endothelium-derived relaxing factor), which in turn causes vasodilation and inhibits platelet aggregation and adhesion, potentially increasing bleeding risks.⁷⁴ Methylene blue, via reduction in the amount and effect of nitric oxide, has been used with success to treat the vasoplegia secondary to a severe protamine reaction. Protamine in excess of heparin can enter the myocardium and decrease cyclic adenosine monophosphate (cAMP), causing myocardial depression.^{13,80} Protamine and protamine–heparin complexes can activate the complement pathway and contribute to vasoactive events.^{13,75} Protamine stimulates mast cells in the human heart and skin to release histamine.^{13,60} Protamine administered in the absence of heparin, or in an amount exceeding that necessary for heparin neutralization, can act as an anticoagulant through several mechanisms. Protamine can impair ADP induced platelet aggregation, clot initiation, clot kinetics, and platelet function, resulting in weaker clot formation.^{44,47,87} Additionally, protamine reduces factor V activation by both thrombin and factor Xa, decreases factor VII^{6,70,71} activation by tissue factor, and enhances tissue-type plasminogen activator mediated fibrinolysis. A trial of patients undergoing CABG reported higher rates of microvascular bleeding and coagulation factor replacement in patients receiving excess protamine.⁵²

Risk factors for protamine induced adverse reactions include prior exposure to protamine in insulin, exposure during previous surgery with protamine reversal, vasectomy, fish allergy, or a rapid of protamine infusion rate.^{56,75} A prospective study reported a 0.06% incidence of anaphylactic reactions to protamine in all patients undergoing CABG, but a 2% incidence in diabetics using neutral protamine Hagedorn (NPH) insulin.¹² A recent systematic review of the literature revealed an anaphylaxis incidence of 1%, but the authors were cautious in interpreting the results because of study heterogeneity.⁷² The resultant elevation of histamine concentrations, the activation of complement, and elevated IgE, IgA,

and IgG concentrations are also suggested as possible mechanisms for the adverse effects.^{54,82,93,94} Diabetic patients receiving daily subcutaneous injections of a protamine containing insulin (NPH) have a 40% to 50% increased risk of immune-mediated adverse reactions, including anaphylaxis.^{28,30,34,42,51,81}

Occasionally, patients manifesting a protamine allergy are incorrectly presumed to have insulin allergy.⁵⁰ In diabetic patients receiving protamine insulin injections, the presence of serum antiprotamine IgE antibody is a significant risk factor for acute protamine reactions. Only patients with previous exposure to protamine insulin injections had serum antiprotamine IgE antibodies. However, in the group without previous protamine insulin exposure, antiprotamine IgG antibody was noted as a risk factor for protamine reactions.⁹⁴ Either naturally occurring cross-reacting antibodies, or perhaps previously unrecognized protamine exposure, was responsible for the generation of these IgG antibodies.

ALTERNATIVES TO PROTAMINE IN PATIENTS AT RISK FOR ADVERSE DRUG REACTIONS

There are limited options to replace protamine for the reversal of heparin in patients who have previously experienced “clinical anaphylaxis” following protamine therapy or in patients who are suspected of being at high risk. Possible strategies include clotting factor replenishment, exchange transfusion in neonates, protamine avoidance, or protamine administration with expectant management of anaphylaxis. Several investigational alternatives include heparin removal devices in the coronary artery bypass extracorporeal circuit, as well as the use of hexadimethrine, methylene blue, platelet factor 4, and heparinase antidotes.^{12,49} Pretreatment with antihistamines and corticosteroids may be sufficient for immune-mediated mechanisms but will probably not be beneficial for pulmonary vasoconstriction and non-immune-mediated anaphylactoid reactions.⁴⁰

PREGNANCY AND LACTATION

Protamine is FDA pregnancy category C. No animal studies have been done on reproduction. Taking into consideration the benefit-risk assessment, protamine may be used to reverse or partially reverse the bleeding in a pregnant woman considered secondary to UFH or LMWH, respectively.⁴ Excretion in breast milk is unknown.

DOSING AND ADMINISTRATION

Dosing in Cardiopulmonary Bypass

Protamine is most frequently used at the conclusion of cardiopulmonary bypass operations to reverse the effects of heparin. Many regimens are used for protamine dosing. These include using arbitrary amounts of protamine and dosing on the basis of the total amount of heparin used, often using a ratio of 0.3 to 1 mg of protamine to 100 units of heparin and subsequently titrating based on activating clotting time (ACT) point-of-care testing.^{22,33,44,57,96}

Dosing in Heparin Rebound and Redosing of Protamine

A heparin anticoagulant rebound effect is noted after cardiopulmonary bypass and is attributed to the presence of detectable circulating heparin several hours after apparently adequate heparin neutralization with protamine. The incidence of heparin rebound and the need for additional protamine range from 4% to 42%, depending on the neutralization protocol.^{32,63,78} It is likely that larger heparin doses may prolong the heparin clearance, contributing to higher than expected heparin concentrations.⁷⁸ When 300 units/kg of body weight doses of heparin were reversed with 3 mg/kg of protamine at the conclusion of cardiopulmonary bypass, a 14% incidence of small but detectable concentrations of circulating heparin was noted at 2 hours, which lasted less than one hour in all but one case.⁶³ A prolonged prothrombin time and thrombocytopenia occurred without increase in hemorrhage.

Dosing for Heparin and Low-Molecular-Weight Heparin

Approximately 1 mg of protamine will neutralize about 100 units (1 mg) of heparin (UFH). In the case of unintentional overdose, the half-life of heparin should be considered, because half of the administered dose of heparin is eliminated within 60 to 90 minutes under normal dosing conditions. In the case of an unintentional overdose without hemorrhage, the short half-life of heparin and the potential risks of protamine diminish the benefit from protamine administration. If protamine is necessary to reverse active hemorrhage, it must be administered very slowly intravenously either undiluted or diluted in D₅W or 0.9% sodium chloride over 10 to 15 minutes to limit the incidence of rate-related hypotension.^{48,76,88}

Several studies suggest incomplete protamine neutralization of the LMWHs enoxaparin, dalteparin, and tinzaparin. Current recommendations are to administer 1 mg of protamine per 100 anti-factor Xa units, where 1 mg enoxaparin equals

100 anti-factor Xa units if administered within 8 hours of the LMWH. A second dose of 0.5 of mg protamine should be administered per 100 anti-factor Xa units if bleeding continues.²³ If more than 8 hours have elapsed, then a smaller dose of protamine can be administered.

A number of tests directly measure heparin concentrations or indirectly measure the effect of heparin on the clotting cascade.^{14,17,22} These tests may be helpful in determining the appropriate protamine dosing. Because excessive protamine can act as an anticoagulant, the dose chosen should be an underestimation of that which is needed.

Dosing in the Overdose Setting

When a patient is believed to have received an overdose of an unknown quantity of heparin, the decision to use protamine should be determined by the presence of a prolonged aPTT and the presence of persistent hemorrhage. The risks of protamine use, especially in those who have had a prior life-threatening reaction to protamine, as well as in a diabetic receiving protamine-containing insulin, and the risks of continued heparin anticoagulation must be weighed. A baseline ACT, thrombin time, heparinneutralized thrombin time, heparin activity, platelets, prothrombin time, partial thromboplastin time, hemoglobin, and hematocrit ideally should be obtained. Because of the routine nature of heparin reversal following cardiopulmonary bypass, consultation with members of the bypass team may be helpful. An empiric dose of protamine may be suggested by the baseline ACT: (a) an ACT of <200 seconds necessitates no protamine, (b) an ACT of 200 to 300 seconds necessitates 0.6 mg/kg, and (c) an ACT of 300 to 400 seconds necessitates 1.2 mg/kg. These doses have not been validated outside of the operative setting. The ACT should be repeated 5 to 15 minutes following protamine administration and in 2 to 8 hours to evaluate for potential heparin rebound. Further dosing should be based on these values.²⁷

When an ACT is unavailable, protamine 25 mg to a maximum of 50 mg can be administered to an adult and adjusted accordingly.⁷⁶ Repeat dosing in several hours may be necessary with heparin rebound. The dose should be administered slowly intravenously over 15 minutes with resuscitative equipment immediately available. Neonates should not receive protamine that has been diluted with bacteriostatic water containing benzyl alcohol.^{6,68,71}

AVAILABILITY

Protamine is available as a parenteral solution ready for injection in a concentration of 10 mg/mL in either a 5 mL or 25 mL vial containing totals of 50 mg and 250 mg, respectively.⁶²

SUMMARY

- Protamine effectively and rapidly reverses the anticoagulant effect of unfractionated heparin.
- Protamine variably reverses the anticoagulant effects of LMWH.
- Protamine has no effect on heparin pentasaccharide fragments or analogs.
- Protamine should only be used for a prolonged aPTT in the presence of active hemorrhage, given the risks of hypotension, anaphylaxis, dysrhythmias, leukopenia, thrombocytopenia, and ARDS.

A17 ANTIDOTES IN DEPTH

High-Dose Insulin Euglycemia

Samuel J. Stellpflug and William Kerns, II

HISTORY

Insulin was discovered and named in 1922, although its existence had been previously surmised. Clinicians at Toronto General Hospital successfully achieved glycemic control in a 14 year-old boy with diabetes by injecting him with pancreatic extract, and this success was the culmination of more than 30 years of research.⁶⁵ In the last two decades, insulin has gained increased attention and importance in the management of a spectrum of critical illnesses, including sepsis, heart failure, and cardiac drug toxicity. The benefits of insulin go well beyond simple control of hyperglycemia. In xenobiotic induced myocardial depression, the use of high dose insulin euglycemia (HIE) of HIE along with sufficient dextrose, can restore normal hemodynamics status.

PHARMACOLOGY

Chemistry/Physiology

To understand the role of insulin specifically for resuscitating patients with cardiac drug toxicity, the altered myocardial physiology that occurs during drug induced shock is briefly reviewed. The hallmarks of severe β -adrenergic antagonist (BAA) and calcium channel blocker (CCB) toxicity are bradycardia and decreased inotropy that compromise cardiac output and produce cardiogenic shock.¹⁵ This is due to direct β -adrenergic receptor antagonism and calcium channel blockade. Peripheral vasodilation can occur as well, especially in the context of dihydropyridine CCB ingestions.^{20,64} In addition to direct receptor and ion channel effects, metabolic derangements may occur that closely resemble diabetes with hyperglycemia, insulin deficiency, insulin resistance, and acidemia.

In the nonstressed state, the heart primarily catabolizes free fatty acids for its energy needs. On the other hand, the stressed myocardium switches its preferred energy substrate to carbohydrates, as demonstrated in models of both BAA and CCB toxicity.^{19,37,61} The greater the degree of shock, the greater the carbohydrate demand.³⁸ The liver responds to stress by making more glucose available via glycogenolysis. As a result, blood glucose concentrations increase. Hyperglycemia is noted both in animal models and in human cases of some cardiac drug overdoses; it can be especially evident with CCB

toxicity.^{9,21,40,62} CCBs interfere with carbohydrate processing by inhibiting pancreatic insulin release, which is necessary to transport glucose across cell membranes. Insulin release from islet cells requires functioning L-type or voltage-gated calcium channels similar to those found in myocardial and vascular tissue. CCBs directly inhibit pancreatic calcium channels (Figs. A17-1A and A17-1B).¹⁴ In vitro models of verapamil infusion confirm this toxicity; circulating glucose concentrations increase without an associated increase in insulin.³⁸ CCBs also create a state of insulin resistance by interfering with glucose transporter 1 (GLUT-1) and phosphatidyl inositol 3-kinase (PI3K) glucose transport (Figs. A17-2A and A17-2B).^{4,42} As a result of diminished circulating insulin and inhibited enzymatic glucose uptake, glucose movement into cells becomes concentration dependent and may not sufficiently support myocardial demand. CCBs further contribute to metabolic abnormalities by inhibiting lactate oxidation.^{37,41} This likely occurs through inhibition of pyruvate dehydrogenase, the enzyme responsible for conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). As a result, pyruvate is preferentially converted to lactate, rather than the acetyl-CoA that would ordinarily enter the Krebs cycle; lactate then accumulates. Lactate accumulation and acidemia are consistent manifestations of CCB toxicity^{15,41} and are also observed in BAA models.¹⁰

FIGURE A17-1A. Insulin (INS) release from the β -pancreatic islet cell is mediated via influx of calcium through voltage-gated (L-type) calcium channels and requires adenosine triphosphate (ATP).

FIGURE A17-1B. CCBs inhibit pancreatic insulin release by antagonizing calcium entry via L-type calcium channel. This results in insufficient insulin to support the glucose demands of the stressed heart and also contributes to hyperglycemia that occurs with CCB toxicity.

FIGURE A17-2A. The binding of insulin (I) to its receptor stimulates glucose entry into cells via a series of phosphorylation reactions involving phosphatidylinositol-3 kinase (PI3K) and protein kinase B (PKB). Ultimately, glucose transporters (GLUTs) are recruited from the cytosol into the cell membrane to facilitate glucose entry.

FIGURE A17-2B. CCBs interfere with the phosphatidylinositol-3 kinase (PI3K) pathway for glucose entry by inhibiting protein kinase B (PKB). Inhibition of this pathway creates a state of insulin resistance and provides one plausible explanation for the need for high doses of insulin (I) to treat drug-induced myocardial depression.

Mechanism of Action

HIE therapy supports the metabolic demands associated with cardiogenic shock and augments calcium processing, thereby increasing myocardial contractility and improving tissue perfusion.

Insulin mediated improved contractility appears to be a critical factor leading to survival from cardiogenic shock. In studies comparing insulin to more traditional therapies such as epinephrine and glucagon, insulin improves cardiac function and work efficiency.^{28,39} Epinephrine and glucagon performed less well, possibly because they promoted free fatty acid utilization. As such, epinephrine and glucagon afforded limited increases in contractility at the expense of less efficient work, increased oxygen demand, and ultimately higher mortality. Interestingly, in BAA and CCB studies using HIE, survival occurs without dramatic improvement in hypotension or bradycardia.^{20,28,37,41} The lack of effect on drug induced hypotension in animal studies and human cases may be due to the vasodilatory properties of insulin.¹⁹ The vasodilatory effects occur in the systemic, coronary, and pulmonary vasculature; this contradicts the occasionally published idea that insulin is a vasopressor. The mechanism is likely due to activation of the PI3K pathway enhancing endothelial nitric oxide synthase (eNOS) activity (Fig. A17-3).^{4,29} Vasodilation in concert with improved cardiac contractility allows for improved tissue perfusion. Improved tissue perfusion may also explain why insulin is associated with superior survival effect as compared with vasopressor adrenergic xenobiotics such as epinephrine.²⁸

FIGURE A17-3. Nitric oxide (NO) is released from endothelial cells in response to insulin. This process involves two kinases: phosphatidylinositol-3 kinase (PI3K) and protein kinase B (PKB). NO diffuses into adjoining vascular smooth muscle cells and binds at a ferric site on the enzyme soluble guanylyl cyclase (sGC). Activation of sGC produces cyclic guanosine monophosphate (cGMP) a signaler of cell relaxation, ultimately leading to vasodilation.

Initially, the ability of insulin to improve cardiac function was attributed to increased catecholamine release. However, evidence does not support this explanation. For example, β -receptor antagonism did not prevent improved contractility that followed insulin administration.^{43,61} In a CCB toxic model, insulin therapy improved cardiac function and survival without increasing circulating catecholamine concentrations.⁴⁰ The preponderance of evidence demonstrates that the positive inotropic effects of insulin occur because of metabolic support of the heart during hypodynamic shock. As alluded to above, during drug-induced shock the heart switches preferred energy precursors from fatty acids to carbohydrates and insulin facilitates this demand.³⁷ Studies demonstrate a direct correlation between carbohydrate metabolism and the improved indices of cardiac function that occur with insulin therapy. Despite β -adrenergic antagonism by propranolol, insulin increased myocardial glucose uptake with subsequent increased contractility.⁶¹ In a model of verapamil toxicity, insulin increased glucose uptake with resultant improved contractility.³⁷ Insulin therapy also increased lactate uptake, most likely by restoring pyruvate dehydrogenase activity.³⁹ In this way, lactate serves as a carbohydrate energy source following conversion to pyruvate and ultimately acetyl-CoA, which can then enter the Krebs cycle.

There is also evidence that insulin may have an effect beyond enhanced carbohydrate usage via direct effects on calcium and, to a lesser extent, potassium and sodium ion homeostasis.^{17,43} It appears that insulin may increase available intracellular calcium by enhancing reverse mode sodium/calcium exchange, with a resultant increase in the sarcoplasmic reticulum (SR) calcium load, thus causing increased contractility.^{31,74} Additionally, there is some support for the idea that this insulin mediated increase in SR calcium availability may not only be due to the reverse mode sodium calcium exchange but also further activation of sodium/hydrogen exchange³¹ (Fig. 61-2).

Pharmacokinetics and Pharmacodynamics

Regular insulin administered as HIE therapy is intravenously given, so gastrointestinal absorption is not an issue. The peak plasma concentration is essentially immediate. The onset and peak of the cardiovascular effect of insulin is roughly 15 to 40 minutes.^{10,28,29,36,41} Insulin is slightly soluble in water, has a volume of distribution of roughly 21 L in an adult human, and demonstrates protein binding of roughly 5%, which can increase in a diabetic patient with insulin antibodies.^{46,63} More than one-half of insulin metabolism occurs in the liver, but there is also a sizable degree that occurs in adipose tissue, muscle, and in the kidneys.⁵⁷ The elimination half-life of intravenously administered insulin is roughly 5 to 10 minutes, and it is partially eliminated in both the kidneys and the bile.^{60,63}

ROLE IN DRUG INDUCED CARDIOVASCULAR TOXICITY

As mentioned above, the positive inotropic effects of insulin were recognized in 1927; however, HIE therapy for drug-induced shock in human was first reported in 1999.^{72,75} This case series included four patients who overdosed on verapamil and one with a combined amlodipine-atenolol overdose. All patients failed traditional antidote therapy but responded to rescue insulin therapy. Since this initial case series, more than 90 cases have been published reporting use of insulin therapy for treatment of isolated or mixed drug induced cardiac drug toxicity.^{1-3,5-8,11-13,16,18,22-27,34,44,45,47-50,52,53,55,56,58,59,62,66-71} Various regimens of classic antidotes were used prior to insulin therapy in many of these cases. No direct outcome comparisons can be made between insulin and these other therapies once thought to be standard care. That being said and recognizing the inherent reporting bias, overall survival was very good when insulin was included in resuscitation. Further review of these cases and animal models yields important clinical information that can be used to guide HIE therapy.

Experimental models suggest that large doses of regular insulin (2.5–10 units/kg/h) may be necessary to provide inotropic support.^{4,10,36,39,41} The most recent human case series utilized 10 units/kg/h as the standard dose.³⁰ In one case, 22 units/kg/h was used with survival after cardiac arrest from nebivolol.⁶⁷ However, humans may respond to less insulin. Most patients in the early reports were treated with HIE ranging between 0.5 and 2 units/kg/h. Many of the literature reported patients received an initial insulin bolus (between 0.1 and 1 unit/kg) prior to continuous infusion. The theoretical advantage to giving an initial insulin bolus is to rapidly saturate insulin receptors to speed the physiological response. Interestingly, one report noted that patients receiving an insulin bolus prior to the infusion showed a better blood pressure response than patients who received only a continuous infusion.²² Three patients received bolus insulin without continuous infusion, including a patient who inadvertently received 1000 units.⁵⁹ In this case, hemodynamics improved and there was no adverse event related to the extreme insulin dose. The typical reported duration of insulin infusion is 24 to 48 hours, with a range of 0.75 to 96 hours. The need for prolonged infusion likely reflects the prolonged toxicokinetics of cardiovascular drugs typically observed following severe overdose.

The predominant clinical effect of insulin was increased cardiac contractility with subsequent improvement in perfusion, often without initial increase in blood pressure. Contractility typically increased within 15 to 40 minutes after initiating insulin and often allowed a decrease in concurrent vasopressor use, sparing the toxicity of those agents. The timing of increased contractility is consistent with the observed response times in animal models.^{10,28,29,36,41} Other salutary effects were observed during insulin therapy. In one case of a combined amlodipine and valsartan overdose, blood pressure increased directly because of increased vascular resistance rather than increased cardiac function.⁶⁶ Two patients converted from third-degree heart block to normal sinus rhythm with increased pulse in temporal relationship to insulin.⁷⁵ Except for these two patients, insulin therapy did not significantly affect heart rate in other reports. One reported case, technically a high-dose insulin failure, strongly supports the idea of insulin as an inotrope.⁶⁸ A patient with baseline hypertrophic cardiomyopathy but no baseline obstructive pathophysiology ingested diltiazem, metoprolol, and amiodarone. With insulin dosing quickly escalated to 10 units/kg/h, there was increased cardiac contractility documented by ultrasonography to the point of inducing hemodynamically significant obstructive outflow. The patient's clinical course ultimately improved following intravenous fat emulsion administration. There have been other cases in which authors reported a lack of response to insulin. Reasons for no response in three of these reports may include inadequate dosing and excessive delay to insulin therapy.¹²

Based on the sum of experimental and clinical experience, we suggest using “off label” HIE (bolus of regular insulin 1 unit/kg followed by 1 to 10 units/kg/h continuous infusion) early in the resuscitation of severe BAA and CCB-induced myocardial depression, simultaneous with traditional pharmacologic and supportive therapies.

ADVERSE EVENTS AND SAFETY ISSUES

The major anticipated adverse event associated with the use of large amounts of insulin, especially in patients naïve to insulin, is hypoglycemia, defined as blood glucose less than 60 mg/dL (3.3 mmol/L) regardless of the presence or absence of symptoms. Because of potential hypoglycemia, all experimental animals received sufficient dextrose during insulin infusion to maintain euglycemia. In the aggregate human cases, patients typically received empiric supplemental dextrose

based on frequent glucose monitoring. The typical dextrose dose was 25 g/h, but requirements varied widely from 0.5 to 75 g/h. The duration of exogenous dextrose supplementation was roughly 2 days, but also varied significantly from 9 to 100 hours. Dextrose supplementation was necessary beyond cessation of insulin for a majority of the documented cases. Despite empiric dextrose and blood glucose monitoring (albeit with no standard frequency of testing), hypoglycemia occurred in some patients. In one retrospective series, hypoglycemia occurred in 5 out of 37 patients and resulted in HIE cessation.⁴⁸ In a prospective evaluation of seven separate CCB overdoses, there was one clinically insignificant episode.²² In another retrospective 12-patient case series, there were 6 patients with a total of 19 hypoglycemic events (8 in one patient), all of uncertain but unlikely clinical significance.³⁰ Of note, dextrose requirement does not directly correlate well with insulin dose or severity of shock. Patients with severe shock and marked hyperglycemia may not need any supplemental dextrose during the initial hours of insulin therapy due to insulin deficiency and insulin resistance. Additionally, there may be a ceiling requirement for dextrose. One animal model demonstrated that dextrose need was greater for animals treated with 5 versus 1 unit/kg/h insulin, but not between groups treated with 5 versus 10 units/kg/h.¹⁰ Overall, hypoglycemia is a potential consequence of HIE therapy, but clinically significant hypoglycemia is rare. A combination of rigorous glucose monitoring and dextrose administration can prevent hypoglycemia and avoid unnecessary cessation of insulin treatment.

Another anticipated consequence of insulin treatment is hypokalemia. Although serum potassium concentrations may fall below normal laboratory ranges, HIE does not typically cause profound hypokalemia. The observed decrease reflects a shifting of potassium from the extracellular to intracellular space that occurs as a result of the action of insulin. Patients maintain normal total body potassium stores and do not experience true deficiency unless they have other reasons for potassium loss. In the initial case series, three patients had a nadir of potassium ranging from 2.2 to 2.8 mEq/L without sequelae.⁷³ In two case series of seven and twelve patients, there were 2/7 and 7/12 patients, respectively, who demonstrated clinically insignificant hypokalemia.^{22,30} There is a theoretical risk of excessive potassium replacement in the instance of lowered serum potassium, but normal total body stores. Hyperkalemia may also worsen verapamil induced myocardial depression.^{33,51}

Other observed ion changes during insulin therapy include hypomagnesemia and hypophosphatemia. Similar to action on potassium, insulin causes an intracellular shift of both phosphorus and magnesium.^{35,54} In the initial series of drug-induced shock treated with insulin, four patients had lowered magnesium (0.4–0.6 mmol/L; normal, 0.8–1.2 mmol/L) and phosphorus (0.2–0.5 mmol/L; normal, 1–1.4 mmol/L) concentrations. No symptoms were attributed to these lowered serum concentrations, but three patients received supplementation of both electrolytes. No other insulin-treated CCB cases address these two electrolytes. Insulin (0.1 units/kg/h) for diabetic ketoacidosis is likewise associated with similar effects on magnesium and phosphorus, so it is unlikely that alterations of magnesium and phosphorus are dose related.³²

PREGNANCY AND LACTATION

Regular insulin is pregnancy category B and is compatible with breastfeeding.

DOSING AND ADMINISTRATION

Based on the experimental studies and aggregate human cases, HIE will most likely benefit patients with cardiac drug induced myocardial depression. Insulin therapy may also be considered for those patients with refractory hypotension due to poor vascular resistance without associated poor contractility. The experimental evidence and human case experience are strongest for CCB toxicity. Animal studies and growing human experience also support its use for BAA intoxication.

Myocardial function can be estimated via emergency department focused cardiac ultrasonography or through machine estimated cardiac output utilizing pulse contour analysis attached to a standard arterial catheter. This can be done less accessibly or more invasively via formal echocardiography or placement of a pulmonary artery catheter. When decreased myocardial function is present, insulin therapy can be used by first administering a 1 unit/kg bolus of regular human insulin along with 0.5 g/kg bolus of dextrose. Patients with markedly elevated blood glucose may not require dextrose support at the initiation of insulin therapy. If blood glucose is greater than 300 mg/dL (16.7 mmol/L), then the dextrose bolus is not necessary. An infusion of regular insulin should immediately follow the bolus starting at 1 unit/kg/h. Ideally, this insulin infusion should be concentrated to prevent fluid overload that may occur with large doses. The authors' institutions concentrate the infusion at 10 unit/mL compared with the typical insulin infusion concentration of 1 unit/mL used for diabetic ketoacidosis. This unusual pharmacy formulation requires close collaboration with hospital pharmacists. A continuous dextrose infusion, beginning at 0.5 g/kg/h, should be concurrently initiated. Dextrose can be started as D₁₀, especially without central venous access and while determining the dextrose need, but it is ultimately best delivered as D₂₅ or D₅₀ via central venous access, also with the intent to lessen large fluid volumes that would otherwise be necessary with administration of more dilute dextrose solutions.

If possible, cardiac function should be reassessed every 10 to 15 minutes after starting HIE therapy. If cardiac function remains depressed, then the insulin dose should be increased. Dosing recommendations typically range up to 10 units/kg/h;

however, doses up to 22 units/kg/h have been used, and the maximum dose is not established.^{10,67} The blood glucose should be monitored every 15 to 30 minutes until stable, and then every 1 to 2 hours. The dextrose infusion should be increased to maintain blood glucose concentrations between 100 and 250 mg/dL (5.5–14 mmol/L) rather than reducing the insulin.

The serum potassium concentration should be measured during HIE therapy. If it is low, especially when potassium loss is suspected, then supplementation is indicated to maintain the concentration in the “mildly hypokalemic” range (2.8–3.2 mEq/L). A reasonable time frame is to evaluate serum potassium hourly while actively titrating the insulin infusion, and every 6 hours once the infusion rate is stabilized. Magnesium and phosphorus can also be measured and supplemented as medically indicated. However, unless there is reason for loss of these three electrolytes, lowered serum concentrations likely reflect compartmental shifts, not depletion.

The ultimate goal of HIE is improvement in organ perfusion as demonstrated by increased cardiac output, improved mental status, adequate urine output, and reversal of metabolic abnormalities, as indicated by serum lactate, bicarbonate, pH, and base excess. This improvement is often, but not always, accompanied by an improvement in mean arterial blood pressure. Because insulin improves both cardiac function and perfusion while slightly vasodilating, treatment goals should focus more on organ perfusion and outcome as opposed to simply the numerical blood pressure. An increase in the rate of dextrose infusion to maintain euglycemia often accompanies hemodynamic and metabolic improvements. This increase in dextrose demand is due, in part, to increased CCB or BAA metabolism and loss of the CCB-induced diabetogenic influences, and can be regarded as a favorable prognostic indicator.

Typical duration of therapy has been 1 to 2 days, although HIE has been used for up to 4 days. We recommend reducing the insulin infusion rate by 1 unit/kg/h once the patient has stabilized, and reassessing hourly for additional infusion reduction while maintaining adequate perfusion. Recognize that the dextrose infusion may be necessary after the insulin is reduced and ultimately eliminated. The reduction of insulin and dextrose may cause potassium shifting which should also be monitored.

SUMMARY

- High-dose insulin euglycemia can be used to augment cardiac function and perfusion in the context of cardiogenic shock due to calcium channel blockers and β -adrenergic antagonists.
- This therapy supports the metabolic demands associated with the cardiogenic shock and augments calcium processing, thereby increasing myocardial contractility and improving tissue perfusion.
- High doses of concentrated regular insulin are intravenously given, along with appropriate amounts of dextrose, and monitoring is required of serum glucose and potassium, in addition to surrogate markers of tissue perfusion, such as cardiac output, urine output, bicarbonate, pH, and lactate.

61 CALCIUM CHANNEL BLOCKERS

David H. Jang and Francis Jerome DeRoos

HISTORY AND EPIDEMIOLOGY

In 1964, Albrect Fleckenstein described an inhibitory action of verapamil and prenylamine on excitation-contraction coupling that was similar to calcium depletion.³ By the late 1970s, the clinical use of calcium channel blockers (CCBs) was widely accepted for variety of cardiovascular indications, including hypertension, dysrhythmias, and angina. Later indications, including Raynaud phenomenon, migraine headaches, and subarachnoid hemorrhage, have been adopted. There are currently 10 individual CCBs marketed in the United States that are available as immediate or sustained-release formulations and as combination products with other antihypertensives.

The cardiovascular drug class is one of the leading classes of drugs associated with poisoning fatality. Over the past 5 years of available data, there were more than 12 million poisonings with more than 7000 poisoning-related deaths reported to the American Association of Poison Control Centers Toxic Exposure Surveillance System. Cardiovascular drugs were involved in more than 474,000 of the reported poisonings and accounted for nearly 18% of the overall poisoning fatalities. Within this class, CCBs were the most common cardiovascular drugs involved in poisoning fatalities. CCBs accounted for more than 50,000 cases reported over the past 5 years, with 289 cases resulting in major effects and more than 100 deaths (Chap. 136).

PHARMACOLOGY

Calcium (Ca^{2+}) ion channels exist as either voltage-dependent or ligandgated channels. There are many types of voltage-gated Ca^{2+} channels that include P, N, R, T, Q, and L-type channels (Table 61–1). Ligand-gated Ca^{2+} channels include IP_3 and ryanodine receptors, which are found intracellularly and play a critical role in cell signaling. Voltage-gated Ca^{2+} channels are located throughout the body in the heart, nervous system, pancreas, and muscles.⁹⁰ The structure of voltage-dependent Ca^{2+} channels is composed of several components that include α_2 , β , δ , and the ion-conducting α_1 -subunit. The α_1 -subunit is the most important component of the Ca^{2+} channel as it contains the actual pore through which Ca^{2+} ions pass and also serves as the binding site of all CCBs. The other subunits such as β and δ act to modulate the function of the α_1 -subunit.^{65,104}

TABLE 61–1. Voltage-Sensitive Calcium Channel Subtypes

Type	Distribution	Function	Blocked By
T (transient)	Polysynaptic nerve terminals and cardiac nodal tissue	Pacemaker activity	Mibefradil
R	Neural tissue	Neurotransmitter release	Cadmium
Q	Presynaptic nerve terminals	Neurotransmitter release	Agatoxin
P (Purkinje)	Cerebellar Purkinje neurons	Neurotransmitter release	Agatoxin
N (neuronal)	Presynaptic nerve terminals	Catecholamine release	ω -Conotoxin
L (long-acting)	Myocardium and smooth muscle	Muscular contraction	Calcium channel blockers

The primary action of all CCBs available in the United States is antagonism of the L-type or “long-acting” voltage-gated Ca^{2+} channels. CCBs are often classified into three groups based on their chemical structure (Table 61–2).^{34,59,65} A fourth class, the tetraols, were developed and included mibefradil, but this drug was withdrawn because of significant adverse drug interactions.⁹⁸ Each group binds a slightly different region of the α_{1c} subunit of the Ca^{2+} channel and thus has different affinities for the various L-type Ca^{2+} channels, both in the myocardium and the vascular smooth muscle. It is often more logical to classify them as nondihydropyridine versus dihydropyridine CCBs. The former includes verapamil and diltiazem, whereas the latter includes many drugs, the chemical names of which all currently end in–pine, such as nifedipine and amlodipine. Verapamil and diltiazem have inhibitory effects on both the sinoatrial (SA) and atrioventricular (AV) nodal tissue and thus are commonly used for the treatment of hypertension, to reduce myocardial oxygen demand, and also to achieve rate control in a variety of tachydysrhythmias.¹ In contrast, the dihydropyridines have very little direct effect on the myocardium at therapeutic doses and act primarily as peripheral vasodilators.¹⁰⁴ They are therefore commonly used as vasodilators for conditions with increased vascular tone such as hypertension, migraine headaches, and postintracranial hemorrhage–associated vasospasm.

TABLE 61–2. Classification of Calcium Channel Blockers Available in the United States

Class	Specific Compounds
Phenylalkylamine	Verapamil (Calan, Isoptin, Verelan)
Benzothiazepine	Diltiazem (Cardizem, Dilacor, Tiazac)
Dihydropyridines	Amlodipine (Norvasc) Clevipine (Cleviprex) Felodipine (Plendil) Isradipine (DynaCirc) Nicardipine (Cardene) Nifedipine (Adalat, Procardia) Nimodipine (Nimotop) Nisoldipine (Sular)
Diarylaminopropylamine ether	Bepidil (Vascor) (withdrawn—QT prolongation)
T-channel blocker	Mibefradil (Posicor) (withdrawn—drug interactions)

Experimental studies suggest an additional vasodilatory effect of some CCBs due to stimulation of nitric oxide release.

Amlodipine and other dihydropyridine CCBs release nitric oxide in a dose-dependent fashion from canine coronary microvessels.^{109,111} Although the exact mechanism is uncertain, it is hypothesized that this amlodipine-induced nitric oxide production results from increasing endothelial nitric oxide synthase activity through phosphorylation of this enzyme. Bradykinin B₂ receptors may also be contributory.¹¹⁰

PHARMACOKINETICS AND TOXICOKINETICS

Absorption. All CCBs are well absorbed orally, but many exhibit low bioavailability due to extensive hepatic first-pass metabolism. Once the CCBs reach the liver, they undergo hepatic oxidative metabolism predominantly via the CYP3A4 subgroup of the cytochrome P450 (CYP) enzyme system.⁶⁴

Distribution. All CCBs are highly protein bound. Volumes of distribution are large for amlodipine (21 L/kg), verapamil (5.5 L/kg), and diltiazem (5.3 L/kg), and somewhat smaller for nifedipine (0.8 L/kg).^{38,69}

Metabolism. Norverapamil, formed by N-demethylation of verapamil, is the only active metabolite and retains 20% of the activity of the parent compound. Diltiazem is predominantly deacetylated into minimally active deacetyldiltiazem, which is then eliminated via the biliary tract.^{39,46} After repeated doses, as well as following overdose, these hepatic enzymes become saturated, reducing the potential of the first-pass effect and increasing the quantity of active drug absorbed systemically.¹⁰⁶ Saturation of metabolism as well as the modified release dosage form contribute to the prolongation of the apparent half-lives reported following overdose of various CCBs.⁷⁹

Excretion. The majority of CCBs undergo a significant amount of renal excretion after metabolism with a small percentage eliminated in the urine unchanged. This varies depending on the CCB. For example, amlodipine undergoes 60% renal excretion after metabolism to inactive metabolites compared with 70% for verapamil (3.4% as unchanged drug) and 90% for nifedipine as inactive metabolites.^{27,66}

One interesting aspect of the pharmacology of CCBs is their potential for drug–drug interactions. CYP3A4, which metabolizes most CCBs, is also responsible for the initial oxidation of numerous other xenobiotics. Verapamil and diltiazem specifically compete for this enzyme and can decrease the clearance of many drugs including carbamazepine, cisapride, quinidine, various β -hydroxy- β -methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, cyclosporine, tacrolimus, most human immunodeficiency virus–protease inhibitors, and theophylline (Chap. 13, Appendix).^{32,76} In June 1998, mibefradil, a structurally unique CCB, was voluntarily withdrawn following several reports of serious adverse drug interactions caused in part by its potent inhibition of CYP3A4.⁵⁵ Other inhibitors of CYP3A4, such as cimetidine, fluoxetine, some antifungals, macrolide antibiotics, and even the flavonoids in grapefruit juice, raise serum concentrations of several CCBs and may result in toxicity.^{31,86}

In addition to affecting CYP3A4, verapamil and diltiazem also inhibit P-glycoprotein–mediated drug transport into peripheral tissue—an inhibition that results in elevated serum concentrations of xenobiotics such as cyclosporine and digoxin that use this transport system (Chap. 13, Appendix). Unlike diltiazem and verapamil, nifedipine and the other dihydropyridines do not appear to affect the clearance of other xenobiotics via CYP3A4 or P-glycoprotein–mediated transport. Similarly, inhibition of P-glycoprotein–mediated transport by certain xenobiotics such as statins result in increased oral bioavailability of CCBs, which may require enhanced monitoring of appropriate patients.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Ca²⁺ plays an essential role in many cellular processes throughout the body as many types of cells depend on the maintenance of a Ca²⁺ concentration gradient across cell membranes in order to function. The extracellular Ca²⁺ concentration is approximately 10,000 times greater than the intracellular concentration. This concentration gradient is important for contraction and relaxation of muscle cells (Fig. 61–1). Ca²⁺ channels located on the cell membrane play a key role to maintain this concentration gradient within muscle cells.^{48,67}

FIGURE 61–1. Normal contraction of myocardial cells. The L-type voltage sensitive calcium channels ($\text{Ca}_v\text{-L}$) open to allow calcium ion influx during myocyte depolarization. This causes the concentration-dependent release of more calcium ions from the ryanodine receptor (RyR) of the sarcoplasmic reticulum (SR).

Ca^{2+} is driven down a large electrical and concentration gradient through L-type Ca^{2+} channels located in all muscle cell types (cardiac, striated, and smooth). This influx of Ca^{2+} is critical for the function of both cardiac and smooth muscle cells; however, skeletal muscle depends primarily on intracellular Ca^{2+} stores for excitation-contraction coupling and not the intracellular influx of Ca^{2+} . In smooth muscle, the rapid influx of Ca^{2+} binds calmodulin, and the resulting complex stimulates myosin light chain kinase activity. The myosin light chain kinase phosphorylates, and thus activates, myosin, which subsequently binds actin, causing a contraction.⁶²

Ca^{2+} plays a similarly important role in myocardial contractility. In myocardial cells, Ca^{2+} influx is slower relative to the initial sodium influx that initiates cellular depolarization, and prolongs this depolarization, creating the plateau phase (phase 2) of the action potential (Chap. 16). The Ca^{2+} subsequently stimulates a receptor operated Ca^{2+} channel on the sarcoplasmic reticulum, known as the ryanodine receptor, releasing Ca^{2+} from the vast stores of the sarcoplasmic reticulum into the cytosol.⁷¹ This is often termed Ca^{2+} -dependent Ca^{2+} release. Ca^{2+} then binds troponin C, which causes a conformational change that displaces troponin and tropomyosin from actin, allowing actin and myosin to bind, resulting in a contraction.^{16,21} Ca^{2+} influx also plays an important role in the spontaneous depolarization (phase 4) of the action potential in the sinoatrial (SA) node. This Ca^{2+} influx also allows normal propagation of electrical impulses via the specialized myocardial conduction tissues, particularly the atrioventricular (AV) node. After opening, the rates of recovery of these slow Ca^{2+} channels, in both the SA and AV nodal tissue, determine the rate of conduction.

The nondihydropyridine CCBs such as verapamil and diltiazem have the greatest affinity for the myocardium, with verapamil considered the most potent. In addition, not only do verapamil and, to a lesser extent, diltiazem impede Ca^{2+} influx and channel recovery in the myocardium, but their blockade is potentiated as the frequency of channel opening increases.^{35,73} Therefore, in a frequently contracting tissue, such as the myocardium, the blockade of verapamil and diltiazem would be augmented.

At therapeutic doses, the dihydropyridine CCBs such as nifedipine have little effect at the myocardium and have most of their effect at the peripheral vascular tissue; thus, they have the most potent vasodilatory effects when compared to the

nondihydropyridine CCBs. Dihydropyridines bind the Ca^{2+} channel best at less-negative membrane potentials. Because the resting potential for myocardial muscle (-90 mV) is lower than that of vascular smooth muscle (-70 mV), dihydropyridines bind preferentially in the peripheral vascular tissue.⁷³

The toxicity of CCBs in poisoning is largely an extension of their therapeutic effects within the cardiovascular system. Inhibition of the L-type Ca^{2+} channels within both the myocardium and peripheral vascular smooth muscle results in a combination of decreased inotropy, heart rate, and arterial vasodilation. Because dihydropyridines have limited myocardial effect at therapeutic concentrations, the baroreceptor reflex remains intact and a slight increase in heart rate and cardiac output may occur. Isradipine is the only dihydropyridine whose inhibitory effect on the SA node is significant enough to blunt any reflex tachycardia. CCB poisoning can also result in blockade of L-type Ca^{2+} channels located in the pancreas. This results in decreased insulin release resulting in hyperglycemia.

CLINICAL MANIFESTATIONS

The hallmark of the CCB poisoning is hypotension and bradycardia, which results from depression of myocardial contraction and peripheral vasodilation.⁸⁴ Myocardial conduction may also be impaired, producing AV conduction abnormalities, idioventricular rhythms, and complete heart block. Junctional escape rhythms frequently occur in patients with significant poisonings.^{13,36,42,75,107} The negative inotropic effects may be so profound, particularly with verapamil, that ventricular contraction may be completely ablated.^{5,10,11,19}

Hypotension is the most common and life-threatening finding in an acute CCB poisoning, typically caused by a combination of decreased inotropy, bradycardia, and peripheral vasodilation.⁷⁸ Patients may also present asymptomatic early following ingestion and subsequently deteriorate rapidly to severe cardiogenic shock.^{5,10,44} The associated clinical findings reflect the degree of cardiovascular compromise and hypoperfusion, particularly to the central nervous system. Early symptoms include fatigue, dizziness, and lightheadedness. Alteration in mentation in the absence of hypotension should prompt the clinician to consider other causes and ingestions. Severely poisoned patients may manifest syncope, altered mental status, coma, and sudden death.^{81,85} Gastrointestinal (GI) effects, such as nausea and vomiting, are not a typical feature of CCB poisoning. Acute respiratory distress syndrome (ARDS) may also occur with severe CCB poisoning. This may be due to precapillary vasodilation with a subsequent increase in transcapillary pressure. The elevated pressure gradient results in increased capillary transudates and possible interstitial edema.^{26,43}

In mild to moderate overdose of dihydropyridine CCBs, the predominantly peripheral effect may induce a reflex tachycardia. However, severe poisoning with any CCBs can result in loss of receptor selectivity resulting in bradycardia. A prospective poison center study noted AV nodal block to occur more frequently with verapamil poisoning.⁷⁸ While deaths are attributed mainly to the nondihydropyridines, a significant number of dihydropyridine-related deaths are also reported.^{58,91} This may reflect the wider use of this latter class of CCBs.

There are several factors that ultimately determine CCB toxicity. These include medication formulation, dose, and coingestion with other cardioactive medications such as β -adrenergic antagonists, underlying comorbidities, and age. Elderly patients and those with underlying cardiovascular disease such as congestive heart failure are more sensitive to CCBs.⁶³ Even at therapeutic doses, these patients are more susceptible to the cardioactive effects of these medications and may develop symptomatic hypotension.

Pediatric cases of CCB are commonly from medication errors or unintentional ingestions of pills found at home.^{12,33} Children with CCB poisoning may develop nonspecific clinical effects such as lethargy, emesis, and confusion. While CCB exposure in children is uncommon, there are reported cases of severe poisoning and death.⁹¹

DIAGNOSTIC TESTING

Any patients with suspected CCB poisoning should be considered at risk for cardiovascular collapse and be evaluated with a 12 lead electrocardiogram (ECG), followed by continuous cardiac and hemodynamic monitoring. A chest radiograph, pulse oximetry, and serum chemistry should also be obtained if any degree of hypoperfusion is suspected. Assessment of electrolytes, including magnesium, and a serum digoxin concentration may be useful in a bradycardic patient with unknown exposure history, although a careful history, if possible, may narrow down the etiology. Cardioactive steroids should be a consideration in the setting of hyperkalemia with normal kidney function. Assays for CCB serum concentrations are not routinely available and therefore have no role in the management of patients poisoned with CCBs.

Hyperglycemia is considered a prognostic sign in cases of severe CCB poisoning. The release of insulin from the β -islet cells in the pancreas is dependent on Ca^{2+} influx through the L-type Ca^{2+} channel. CCB poisoning reduces insulin release with resultant hyperglycemia. An additional mechanism may be dysregulation of the insulin dependent phosphatidylinositol 3-kinase pathway.¹¹ It should be noted that hyperglycemia might also be the result of diabetes or the administration of glucagon for suspected β -adrenergic antagonist poisoning.

A retrospective study suggests that serum glucose concentration correlate with the severity of CCB poisoning. The initial mean serum glucose concentration was 188 mg/dL in patients who met a composite end point of requiring vasopressors, a pacemaker, or death, versus 122 mg/dL in those not requiring intervention. Peak serum glucose concentrations were also significantly different.⁵⁷ This finding may become a useful early sign of severity and an indicator for when to initiate hyperinsulinemia-euglycemia therapy.

MANAGEMENT

General Approach

All patients with suspected CCB poisoning should undergo prompt evaluation even when the initial vital signs are normal. This urgency is due to the potential to initiate early GI decontamination and pharmacologic therapies before patients manifest severe poisoning. This is particularly important with ingestions involving sustained-release formulations. Intravenous access should be obtained and initial treatment should be directed toward aggressive GI decontamination of patients with large recent ingestions. All patients who become hypotensive should receive a fluid bolus of 10 to 20 mL/kg of crystalloid which should be repeated as needed. Caution is required, as aggressive fluid resuscitation should not be given to patients with congestive heart failure, evidence of ARDS, or chronic kidney disease (CKD).

Pharmacotherapy should focus on maintenance or improvement of both cardiac output and peripheral vascular tone. Although atropine, calcium, insulin, glucagon, isoproterenol, dopamine, epinephrine, norepinephrine, and phosphodiesterase inhibitors have been used with reported success in CCB-poisoned patients, no single intervention has consistently demonstrated efficacy. It is also important to be aware that certain treatment such as vasopressors may be detrimental with long-term use, so these should be avoided when there are more effective and safer treatment options.

Although therapy for hypotension and bradycardia should begin with crystalloids and atropine, most critically poisoned patients will not respond to these initial efforts and will require further pharmacotherapy. While it would be ideal to initiate each therapy individually and monitor the patient's hemodynamic response, in the most critically ill patients, multiple therapies should be administered simultaneously. A reasonable treatment sequence based on existing data and clinical experience should initially consist of isotonic fluids, atropine, glucagon, and calcium. If the patient does not respond to these initial treatments, hyperinsulinemia-euglycemic therapy should be initiated. In cases of refractory shock or in cardiac arrest, the use of 20% intravenous fat emulsion should be considered. The use of vasopressors such as norepinephrine or dopamine can result in tissue ischemia with long-term use and thus should be avoided. Phosphodiesterase inhibitors such as inamrinone, milrinone, and enoximone have been used to treat CCB poisoning.^{54,82,103} These xenobiotics inhibit the breakdown of cAMP by phosphodiesterase, thereby increasing intracellular cAMP concentrations, resulting in increased cardiac output. Despite some reported success, phosphodiesterase inhibitors are not readily available, and there are other xenobiotics that are more effective and easier to utilize (Fig. 61–2).

FIGURE 61–2. Myocardial toxicity of calcium channel blockers and use of antidotal therapies. Calcium channel blockers

reduce calcium ion influx through the L-type calcium channel ($\text{Ca}_v\text{-L}$) and thus reduce contractility. The entry of calcium via voltage-sensitive channels ($\text{Ca}_v\text{-L}$) initiates a cascade of events that result in actin-myosin coupling and contractions. Mechanisms to increase intracellular calcium include recruitment of new or dormant calcium channels by increasing cyclic adenosine monophosphate (cAMP) by stimulating its formation by adenylyl cyclase (AC) with glucagon (see text). The use of calcium salts may increase the calcium concentration gradient across the cellular membrane to further its influx and improve contractility. The mechanism by which insulin therapy enhances inotropy is not fully known. $5'\text{MP} = 5'$ -monophosphate; PDEI = phosphodiesterase inhibitor; PKA = protein kinase A; RyR = ryanodine receptor; SR = sarcoplasmic reticulum.

Gastrointestinal Decontamination

Because CCB poisoning is a leading cause of poisoning fatality, attempts to prevent absorption from the GI tract should be strongly considered, assuming there are no contraindications for the described techniques below. This is particularly important if sustained-release CCBs are suspected. Patients who present early with minimal or no symptoms can have delayed cardiovascular toxicity, which can be profound and refractory to conventional treatment, making early GI decontamination a cornerstone in CCB management.

Induced emesis is contraindicated because CCB-poisoned patients can rapidly deteriorate. Orogastric lavage should be considered for all patients who present early (1–2 hours postingestion) after large ingestions and for those who are critically ill and require immediate endotracheal intubation. Although the effects of orogastric lavage following overdose of a sustained-release CCB have not been specifically studied, given the toxicity of CCB poisoning, orogastric lavage should still be strongly considered. When performing orogastric lavage in a CCB-poisoned patient, it is important to remember that lavage may increase vagal tone and potentially exacerbate any bradydysrhythmias.⁹⁴ Pretreatment with a therapeutic dose of atropine may therefore be desirable.

All patients with CCB ingestions should receive 1 g/kg of activated charcoal orally or via nasogastric tube as long as the airway is stable or protected. Multiple-dose activated charcoal (MDAC) (0.5 g/kg every 4–6 hours) without a cathartic should be administered for nearly all patients with either sustained-release pill ingestions or signs of continuing absorption. Although data are limited, there is no evidence that MDAC increases CCB clearance from the serum.⁷⁹ Rather, its efficacy may be a result of the continuous presence of activated charcoal throughout the GI tract, which adsorbs any active xenobiotic from its slow-release formulation. MDAC should not be administered to a patient with inadequate GI function (eg, hypotension, diminished peristalsis sounds (Antidotes in Depth: A1)).

WBI with polyethylene glycol solution (1–2 L/h orally or via nasogastric tube in adults, up to 500 mL/h in children) should be initiated for patients who ingest sustained-release products and for whom there are no contraindications.¹⁵ Administration should be continued until the rectal effluent is clear (Antidotes in Depth: A2).

Atropine

Atropine is often first-line medication for patients with symptomatic bradycardia from xenobiotic poisoning such as organic phosphorus compounds, β -adrenergic antagonists, and calcium channel blockers. While the use of atropine improved both heart rate and cardiac output in an early dog model of verapamil poisoning and a few patients with bradycardia from CCB poisoning,^{30,77} reports of patients with severe CCB poisoning demonstrate atropine to be largely ineffective.^{45,74,89} The decreased effectiveness may be largely due to the negative inotropic effects and/or peripheral vasodilation of CCBs. Given its availability, familiarity, efficacy in mild poisonings, and safety profile, atropine should be considered as initial therapy in patients with symptomatic bradycardia.

Dose. The dosing of atropine for xenobiotic induced bradycardia is similar to the dose used for Advanced Cardiac Life Support. Dosing should begin with 0.5 to 1.0 mg (minimum of 0.1 mg; 0.02 mg/kg in children) intravenously every 2 or 3 minutes up to a maximum dose of 3 mg in all patients with symptomatic bradycardia. However, treatment failures should be anticipated in severely poisoned patients. In patients in whom whole-bowel irrigation (WBI) or MDAC will be used, the use of atropine must be carefully considered, weighing the potential benefits of improved heart rate, and thus cardiac output, against the anticholinergic effects with potential decreased GI motility.

Calcium

Ca^{2+} is another treatment often utilized for CCB poisoning to increase in extracellular Ca^{2+} concentration with an increase in transmembrane concentration gradient. Pretreatment with intravenous Ca^{2+} prevents hypotension without diminishing the antidysrhythmic efficacy prior to therapeutic verapamil use in reentrant supraventricular tachydysrhythmias.^{22,88} This also is observed with CCB poisoning where Ca^{2+} tends to improve blood pressure more than heart rate. Experimental models have also demonstrated the utility of Ca^{2+} salts with CCB poisoning. In verapamil-poisoned dogs, improvement in inotropy and blood pressure was demonstrated after increasing the serum Ca^{2+} concentration by 2 mEq/L with an intravenous infusion of

10% calcium chloride (CaCl_2) at 3 mg/kg/min.^{30,36}

Clinical experience demonstrates that Ca^{2+} reverses the negative inotropy, impaired conduction, and hypotension in many humans poisoned by CCBs.^{56,60,79} Unfortunately, this effect is often short lived, and more severely poisoned patients may not improve significantly with Ca^{2+} administration alone.^{18,45,83} Although some authors believe that these failures might represent inadequate dosing, optimal effective dosing of Ca^{2+} is unclear and they recommend repeat doses of Ca^{2+} to markedly increase the serum ionized Ca^{2+} concentrations.^{42,56} The excessive use of Ca^{2+} can result in significant complications, particularly if a Ca^{2+} infusion is used.⁸⁷ Caution should be exercised in the administration of Ca^{2+} in patients who may have suspected acute cardioactive steroid poisoning as a cause of their bradycardia.¹⁴ The use of Ca^{2+} in the setting of cardioactive steroid poisoning may result in cardiac complications such as asystole (Chap. 65).

Dose. Recommendations for poisoned adults include an initial intravenous infusion of approximately 13 to 25 mEq of Ca^{2+} (10–20 mL of 10% CaCl_2 or 30–60 mL of 10% Ca^{2+} gluconate) followed by either repeat boluses every 15 to 20 minutes up to three to four doses or a continuous infusion of 0.5 mEq/kg/h of Ca^{2+} (0.2–0.4 mL/kg/h of 10% CaCl_2 chloride or 0.6–1.2 mL/kg/h of 10% Ca^{2+} gluconate) (Antidotes in Depth: A29). Careful selection and attention to the type of Ca^{2+} used is critical for dosing. Although there is no difference in efficacy of CaCl_2 or calcium gluconate, 1 g of CaCl_2 contains 13.4 mEq of Ca^{2+} , which is about three times the 4.65 mEq found in 1 g of calcium gluconate. Thus, in order to administer equal doses of Ca^{2+} , three times the volume of calcium gluconate compared with that of CaCl_2 is required. The main limitation of using CaCl_2 , however, is that it has significant potential for causing tissue injury if extravasated, so administration should ideally be via central venous access. Adverse effects of intravenous Ca^{2+} include nausea, vomiting, flushing, constipation, confusion, hypercalcemia, and hypophosphatemia.

Glucagon

Glucagon is an endogenous polypeptide hormone secreted by the pancreatic alpha-cells in response to hypoglycemia and catecholamines. In addition, it has significant inotropic and chronotropic effects (Antidotes in Depth: A18).^{17,92,108} Glucagon is a therapy of choice for β -adrenergic antagonist poisoning (Chap. 62) because of its ability to bypass the β -adrenergic receptor and activate adenylate cyclase via a G_s protein in the myocardium.¹⁰⁵ Thus, glucagon is unique in that it is functionally a “pure” β_1 agonist, with no peripheral vasodilatory effects (Fig. 61–2). There are reports of both successes and failures of glucagon in CCB-poisoned patients who failed to respond to fluids, Ca^{2+} , or dopamine and dobutamine.^{19,23,37,45}

Dose. Dosing for glucagon is not well established.⁶ An initial dose of 3 to 5 mg IV, slowly over 1 to 2 minutes, is reasonable in adults, and if there is no hemodynamic improvement within 5 minutes, retreatment with a dose of 4 to 10 mg may be effective. The initial pediatric dose is 50 $\mu\text{g/kg}$. Because of the short half-life of glucagon, repeat doses may be useful. A maintenance infusion should be initiated once a desired effect is achieved. Adverse effects include vomiting and hyperglycemia, particularly in diabetics or during continuous infusion. In addition, patients who receive repeat administration develop tachyphylaxis, which is an acute decrease in response to a drug after repeated administration.

Insulin-Euglycemia Therapy

Insulin-euglycemia or high-dose insulin-euglycemia (HIE) therapy has become the treatment of choice for patients who are severely poisoned by CCBs. Healthy myocardial tissue relies predominantly on free fatty acids for its metabolic needs, and CCB poisoning forces it to become more carbohydrate dependent.^{49,50,52,53} At the same time, CCBs inhibit Ca^{2+} -mediated insulin secretion from the β -islet cells in the pancreas, making glucose uptake in myocardial cells dependent on passive diffusion down a concentration gradient rather than insulin-mediated active transport.²⁰ In addition, there is evidence that the CCB-poisoned myocardium also becomes insulin resistant, possibly by dysregulation of the phosphatidylinositol 3 kinase pathway (Antidotes in Depth: A17). This may prevent normal recruitment of insulin-responsive glucose transporter proteins. The combination of inhibited insulin secretion and impaired glucose utilization may explain why severe CCB toxicity often produces significant hyperglycemia.^{51,52}

Many CCB-poisoned patients have been successfully treated with HIE therapy as demonstrated by improved hemodynamic function, mainly resulting from improved contractility, with little effect on heart rate. There are also reports of the failure of this treatment, but this may represent initiation of therapy in terminally ill patients with multiple organ failure.^{28,45}

Dose. Although the dose of insulin is not definitively established, therapy typically begins with a bolus of 1 unit/kg of regular human insulin along with 0.5 g/kg of dextrose. If blood glucose is greater than 300 mg/dL (16.65 mmol/L), the dextrose bolus is unnecessary. An infusion of regular insulin should follow the bolus starting at 1.0 units/kg/h titrated up to 2 units/kg/h if no improvement after 30 minutes. Some authors advocate the use of even higher doses (10 units/kg) of

insulin.²⁵ A continuous dextrose infusion, beginning at 0.5 g/kg/h, should also be started. Glucose should be monitored every 30 minutes for the first 4 hours and titrated to maintain euglycemia. The response to insulin is typically delayed for 15 to 60 minutes, so the use of HIE should be considered very early in the patient's course if severe CCB poisoning is suspected. Primary complications of HIE include hypoglycemia and hypokalemia from intracellular shifting of potassium. It is essential to note that the development of hypoglycemia is an indication to increase glucose delivery rather than decrease the insulin infusion rate.

Intravenous Fat Emulsion

Intravenous fat emulsion (IFE) has been used as a source of parenteral nutrition and as a diluent for intravenous drug delivery of highly lipophilic medications such as propofol and liposomal amphotericin.²⁴ The use of IFE as an antidote is most extensively studied for the treatment of local anesthetic toxicity, specifically from bupivacaine, but has been utilized in overdoses from other lipophilic drugs such as psychiatric medication, calcium channel blockers, and β -adrenergic antagonists.

IFE is a white, milky liquid composed of two types of lipids, triglycerides and phospholipids. It is sterile and nonpyrogenic with a pH of about 8 (range, 6–9). IFEs are isotonic solutions (260–310 mOsm/L) and are available in 5%, 10%, 20%, and 30% solutions.⁹⁷ There are three proposed mechanisms of action for IFE: activation of ion channels (calcium); enhancement of intracellular metabolism⁹⁵; and acting as a lipid sink to sequester lipid-soluble drugs. The latter mechanism is the most likely explanation based on existing literature.

An important property of medications that may determine the effectiveness of IFE is lipophilicity. Lipophilicity means the tendency of a drug to partition between lipophilic organic phase and the polar aqueous phase, and value of lipophilicity most commonly refers to logarithm of partition coefficient P (logP) between these two phases. For ionizable compounds, the partition is changed as a function of pH; this relationship is called a distribution constant (logD) or sometimes also as an apparent partition coefficient. Drugs that are highly lipophilic may benefit more from the use of IFE in severe poisoning. Table 61–3 lists major CCBs with their logD and logP values.

TABLE 61–3. LogP and LogD of Commonly Available Calcium Channel Blockers

<i>Calcium Channel Blocker</i>	<i>LogP</i>	<i>LogD at pH 7</i>
Amlodipine	3.72	2.00
Bepridil	6.43	4.27
Diltiazem	4.53	2.64
Felodipine	4.92	4.92
Isradipine	3.68	3.67
Nicardipine	5.22	4.68
Nimodipine	3.94	3.94
Verapamil	4.91	2.91

Existing experimental evidence supports that IFE decreases the toxicity of a few lipid-soluble drugs, most notably bupivacaine.^{100,101} Pretreatment with IFE also increased the dose of certain medications to cause toxicity.¹⁰² Other models suggest that IFE is an effective therapy for CCB-poisoned patients. In a controlled study of rodents that were poisoned with

verapamil, the use of IFE resulted in both increased survival and heart rate when compared to the control groups.^{9,70,93} IFE was also used on a patient with severe verapamil poisoning who failed Ca^{2+} and HIE but when given IFE showed improvement and survival. Serum verapamil concentrations were measured before and after IFE treatment. There was a decrease in verapamil after IFE administration once the lipid was removed from the samples, which demonstrate sequestration of verapamil²⁸ (Antidotes in Depth: A20).

Dose. The recommended dose of IFE is a 1.5 mL/kg bolus. The bolus can be repeated several times for persistent asystole followed by an infusion of 0.25 mL/kg/min or 15 mL/kg/h to run for 30 to 60 minutes. IFE has only traditionally been given to patients in extremis from an overdose, but at this time IFE should be considered in patients who are persistently unstable despite the use of other therapies such as HIE.

Adjunctive Pharmacologic Treatment

Other pharmacotherapies have been studied in the setting of CCB poisoning. There are limited data with these therapies, and they should be considered only when all of the above treatments have failed. Digoxin has been experimentally evaluated in CCB poisoning since it raises the intracellular Ca^{2+} concentration.^{7,8} In a canine model of verapamil poisoning, digoxin, in conjunction with atropine or Ca^{2+} , improved both systolic blood pressure and myocardial inotropy.⁷ However, because digoxin requires a significant amount of time to distribute into tissue, and because limited efficacy data and no safety data have yet been collected, more evaluation is needed before digoxin is administered to patients with CCB poisoning. Another xenobiotic that has been utilized as a treatment for CCB poisoning is levosimendan. Levosimendan is a Ca^{2+} sensitizer used in the management of acutely decompensated congestive heart failure. While there are reported cases of success with the use of this drug, there is also existing experimental evidence that does not support its use.^{2,68,96}

Most recently, methylene blue was reported in a confirmed ingestion of amlodipine poisoning in a patient that failed conventional therapy, including HIE treatment. A Swan-Ganz catheter confirmed pure vasodilatory shock, which responded to methylene blue (2 mg/kg).⁴⁵ Methylene blue is also reported with success in a case of a mixed β -blocker and CCB overdose,⁴ and it is used in other states of refractory vasodilatory shock such as anaphylaxis and sepsis due to inhibition of methylene blue along the nitric oxide–cyclic guanosine monophosphate pathway. There is some evidence to suggest certain dihydropyridines such as amlodipine mediate its vasodilatory effects via nitric oxide, but the importance of this pathway in acute poisoning is unclear. Further investigation is required before methylene blue can routinely be recommended in patients with CCB poisoning.

Inotropes and Vasopressors

Catecholamines are often administered once first-line therapy such as atropine, Ca^{2+} , glucagon, and isotonic fluids fail. There are numerous cases that describe either success or failure with various agents, including epinephrine, norepinephrine, dopamine, isoproterenol, dobutamine, and vasopressin.^{18,37,41,61} Based on experimental and clinical data, no single xenobiotic is consistently effective. The variability in response is from the differences of CCB involved, coingestants with other cardioactive medications, and patient response. CCB poisoning may involve the myocardium (verapamil and diltiazem) mediated by β_1 -adrenergic receptors, resulting in negative chronotrophy/inotrophy and/or peripheral smooth muscle relaxation (dihydropyridines) with vasodilation mediated by α_1 -adrenergic receptors. Despite variable success in CCB poisoning, the existing data described previously show that all vasopressors are generally inferior with significantly more adverse effects such as tissue ischemia with long-term use.

Adjunctive Hemodynamic Support

The most severely CCB-poisoned patients may not respond to any pharmacologic intervention. Transthoracic or intravenous cardiac pacing may be required to improve heart rate, as several case reports demonstrate.^{89,99} However, in a prospective cohort of CCB poisonings, two of four patients with significant bradycardia requiring electrical pacing had no electrical capture.⁷⁷ In addition, even if electrical pacing is effective in increasing the heart rate, blood pressure often remains unchanged.^{40,41}

Intraaortic balloon counterpulsation is another invasive supportive option to be considered in CCB poisoning refractory to pharmacologic therapy.⁴⁷ Intraaortic balloon counterpulsation was used successfully to improve cardiac output and blood pressure in a patient with a mixed verapamil and atenolol overdose.²⁹

Severely CCB-poisoned patients have also been supported for days and subsequently recovered fully with much more invasive and technologically demanding extracorporeal membrane oxygenation (ECMO) and emergent open and percutaneous cardiopulmonary bypass.^{40,80} The major limitation of all these technologies, however, is that they are available only at tertiary care facilities.

Molecular adsorbents recirculating system (MARS) therapy is a specific extracorporeal albumin dialysis that is reported in the treatment of severe CCB poisoning. MARS therapy has the unique ability to selectively remove from

circulation protein-bound xenobiotics that are not cleared by conventional hemodialysis. The use of MARS therapy is under current investigation with *Amanita* poisoning but reportedly was successfully utilized in three patients with severe nondihydropyridine CCB poisoning.⁷²

DISPOSITION

Patients who manifest signs or symptoms of toxicity should be admitted to an intensive care setting. Because of the potential for delayed toxicity, patients who ingest sustained-release products should be admitted for 24 hours to a monitored setting, even if asymptomatic. This precautionary approach is particularly important for toddlers and small children in whom even one or a few tablets may produce significant toxicity. Criteria for safe discharge or medical clearance apply only to patients with a reliable history of an ingestion of an “immediate-release” preparation who have received adequate GI decontamination, had serial ECGs over 6 to 8 hours that have remained unchanged, and are asymptomatic.

SUMMARY

- The hallmarks of CCB toxicity include bradydysrhythmias and hypotension, which are an extension of their pharmacologic effects.
- Although most patients develop symptoms of hypoperfusion, such as lightheadedness, nausea, or fatigue, within hours of a significant ingestion, ingestion of sustained-release formulations may result in significant delays in any hemodynamic consequences and may prolong toxicity.
- Aggressive decontamination of patients with exposures to sustained-release products should begin as soon as possible and should not be delayed while awaiting signs of toxicity.
- The early use of high-dose insulin therapy should be instituted with attempts to avoid the use of vasopressors as it requires time for the effects to occur. In cases of severe toxicity, the use of intravenous fat emulsion therapy should be considered.
- Patients who fail to respond to all pharmaceutical interventions should be considered for adjunctive hemodynamic support whenever available.

62 β -ADRENERGIC ANTAGONISTS

Jeffrey R. Brubacher

HISTORY

In 1948, Raymond Alquist postulated that the cardiovascular actions of epinephrine, hypertension and tachycardia, were best explained by the existence of two distinct sets of receptors that he generically named α and β receptors. At that time, the contemporary “antiepinephrine” xenobiotics such as phenoxybenzamine reversed the hypertension but not the tachycardia associated with epinephrine. According to Alquist’s theory these xenobiotics acted at the α receptors. The β receptors, in his schema, mediated catecholamine induced tachycardia. The British pharmacist, Sir James Black was influenced by Alquist’s work and recognized the potential clinical benefit of a β -adrenergic antagonist. In 1958, Black synthesized the first β -adrenergic antagonist, pronethalol. This drug was briefly marketed as Alderlin, named after Alderly Park, the research headquarters of ICI Pharmaceuticals. Pronethalol was discontinued because it produced thymic tumors in mice. Propranolol was soon developed and marketed as Inderal (an incomplete anagram of Alderlin) in the United Kingdom in 1964.^{22,199} and in the United States in 1973. Prior to the introduction of β -adrenergic antagonists, the management of angina was limited to medications such as nitrates, which reduced preload through dilation of the venous capacitance vessels and increased myocardial oxygen delivery by vasodilation of the coronary arteries. Propranolol gave clinicians the ability to decrease myocardial oxygen utilization. This new approach proved to decrease morbidity and mortality in patients with ischemic heart disease.¹¹² New drugs soon followed and by 1979 there were ten β -adrenergic antagonists available in the United States.⁵⁴ Unfortunately it soon became apparent that these medications were dangerous

when taken in overdose and by 1979 cases of severe toxicity and death from β -adrenergic overdose were reported.⁵⁴ Today there are nineteen β -adrenergic antagonists approved by the US Food and Drug Administration, and other β -adrenergic antagonists are available worldwide (Table 62–1). The pharmacology, toxicology, and poison management issues discussed in this chapter are applicable to all of these drugs. They are commonly used in the treatment of cardiovascular disease: hypertension, coronary artery disease, and tachydysrhythmias. Additional indications for β -adrenergic antagonists include congestive heart failure, migraine headaches, benign essential tremor, panic attack, stage fright, and hyperthyroidism. Ophthalmic preparations containing β -adrenergic antagonists are used in the treatment of glaucoma.⁸⁰

TABLE 62–1. Pharmacologic Properties of the β -Adrenergic Antagonists

	Adrenergic Blocking Activity	Partial Agonist Activity (ISA)	Membrane Stabilizing Activity	Vasodilating Property	Log <i>P</i> ^a	Protein Binding (%)	Oral Bioavailability (%)	Half-Life (hours)	Metabolism	Volume of Distribution (L/kg)
Acetazolol	β ₁	Yes	Yes	No	0.53	25	40	2–4	Hepatic/renal	1.2
Atenolol	β ₁	No	No	No	–2.03	<5	40–50	5–9	Renal	1
Betasolol (tablets and ocular drops)	β ₁	No	Yes	Yes (calcium channel blockade)	0.56	50	30–90	14–22	Hepatic/renal	4.9–8.8
Bisoprolol	β ₁	No	No	No	0.11	30	80	9–12	Hepatic/renal	3.2
Bucindolol	α, β ₁ , β ₂	β ₁ agonism		Yes (β ₁ agonism and α ₁ blockade)	—		30	8 ± 4.5	Hepatic	//
Carteolol ophthalmic	β ₁ , β ₂	Yes	No	Yes, partial (β ₁ agonism and nitric oxide mediated)	–0.42	30	35	5–6	Renal	//
Carvedilol (long acting form available)	α, β ₁ , β ₂	No	Yes	Yes (α ₁ blockade, calcium channel blockade)	3.16	–98	25–35	6–10	Hepatic	115
Celiprolol	α, β ₁	β ₁ agonism		Yes (β ₁ agonism, nitric oxide mediated)	—	22–24	30–70	5	Hepatic	//
Esmolol	β ₁	No	No	No	–0.22	50	//	– 8 minutes	RBC esterases	2
Labetalol	α, β ₁ , β ₂	β ₁	Low	Yes (α ₁ blockade, β ₁ agonism)	0.99	50	20–33	4–8	Hepatic	9
Levobundolol ophthalmic	β ₁ , β ₂	No	No	No	0.56	//	//	6	//	//
Metipranolol ophthalmic	β ₁ , β ₂	No	No	No	0.53	//	//	3–4	//	//
Metoprolol (long acting form available)	β ₁	No	Low	No	–0.34	10	40–50	3–4	Hepatic	4
Nadolol	β ₁ , β ₂	No	No	No	–0.84	20–30	30–35	10–24	Renal	2
Nebivolol	β ₁	No		Yes (nitric oxide mediated)	—	98	12–96	8–32	Hepatic	10–40
Oxprenolol	β ₁ , β ₂	Yes	Yes	No	—	80	20–70	1–3	Hepatic	1.3
Pembolol	β ₁ , β ₂	Yes	No	No	2.05	90	– 100	5	Hepatic/renal	//
Pindolol	β ₁ , β ₂	Yes	Low	No	–0.19	50	75–90	3–4	Hepatic/renal	2
Propranolol (long acting form available)	β ₁ , β ₂	No	Yes	No	0.99	90	25	3–5	Hepatic	4
Sotalol	β ₁ , β ₂	No	No	No	–1.82	0	90	9–12	Renal	2
Timolol (tablets and ophthalmic)	β ₁ , β ₂	No	No	No	–1.99	60	75	3–5	Hepatic/renal	2

Agents in italics are not FDA approved. Information from References 35, 57, 75, 140, 146, 148, 152, 270, 273. The symbol “//” indicates that information is not available.

^aLog *P* is the octanol/water partition coefficient at pH 7.

EPIDEMIOLOGY

Intentional β -adrenergic antagonist overdose, although relatively uncommon, continues to account for a number of deaths annually. From 1985 to 1995, there were 52,156 β -adrenergic antagonist exposures reported to the American Association of Poison Control Centers (AAPCC; Chap. 136). These exposures accounted for 164 deaths of which β -adrenergic antagonists were implicated as the primary cause of death in 38. The other fatalities could not be clearly ascribed to β -adrenergic antagonists due to cardioactive coingestants such as calcium channel blockers or other factors. Children under the age of 6 accounted for 19,388 exposures, but no fatalities were reported in this age group. The youngest fatality reported in this series was aged 7 years. It is interesting to note that more than one-half of the fatalities developed cardiac arrest after reaching health care personnel.¹³³ The number of exposures to β -adrenergic antagonists reported to the AAPCC has increased annually from 9500 in 1999 to more than 23,000 in 2010. Just under one-half of these exposures were single substance ingestions. Each year since 2006, single substance exposures to β -adrenergic antagonists have resulted in between 54 and 70 cases with major morbidity and three to six fatalities (Chap. 136).

Compared with the other β -adrenergic antagonists, propranolol accounts for a disproportionate number of cases of self-poisoning^{36,167} and deaths.^{109,133} This may be explained by the fact that propranolol is frequently prescribed to patients with diagnoses, such as anxiety, stress, hyperthyroidism, and migraine, who may be more prone to suicide attempts.¹⁶⁷ Propranolol is also more lethal due to its lipophilic and membrane stabilizing properties.^{75,167}

PHARMACOLOGY

Cardiac Cycle

Normal cardiac electrical activity involves a complex series of ion fluxes that result in myocyte depolarization and repolarization. Cardiac electrical activity is coupled to myocyte contraction and relaxation respectively by increases and decreases in intracellular calcium concentrations. Cardiac electrical and mechanical activity is closely regulated by the autonomic nervous system.

Under normal conditions, heart rate is determined by the rate of spontaneous discharge of specialized pacemaker cells that comprise the sinoatrial (SA) node (Fig. 62–1). Pacemaker cells are also found in the atrioventricular (AV) node and in Purkinje fibers. Spontaneous pacemaker cell depolarization has traditionally been ascribed to inward cation current through “pacemaker channels.”^{2,43} Recent research suggests that spontaneous depolarization of pacemaker cells involves several mechanisms including a “membrane clock,” consisting of “pacemaker channels” and other inward cation channels located on the cell membrane, and a “calcium clock,” which is driven by rhythmic release of calcium from the sarcoplasmic reticulum.^{35,111,117,140} β -Adrenergic stimulation significantly increases the rate of pacemaker cell depolarization by phosphorylating proteins within the sarcoplasmic reticulum, thereby increasing the rate of the “calcium clock.” There is also a direct, phosphorylation-independent action of cyclic adenosine monophosphate (cAMP) at the pacemaker channels, which increases the rate of the “membrane clock.”³⁵ Depolarization of cells in the SA node spreads to surrounding atrial cells where it triggers the opening of fast sodium channels. This initiates an electric current that spreads from cell to cell along specialized pathways to depolarize the entire heart. This depolarization, referred to as cardiac excitation, is linked to mechanical activity of the heart by the process of electrical–mechanical coupling described below (Chap. 16).

FIGURE 62–1. Cardiac conduction system: A. The cardiac cycle begins when pacemaker cells in the sinoatrial node depolarize spontaneously. Traditionally, this depolarization has been attributed to inward “pacemaker” currents (I_f). There is recent evidence that that pacemaker cell depolarization may also be driven by cyclical calcium release from a “calcium clock” in the sarcoplasmic reticulum (SR). β -Adrenergic stimulation increases both the frequency of the “calcium clock” by a phosphokinase A (PKA) mediated effect and the magnitude of the pacemaker current secondary to a direct effect of cAMP. These effects both increase the heart rate. Cholinergic stimulation has the opposite effects and results in

bradycardia. Pacemaker cells lack fast sodium channels. Pacemaker cell depolarization triggers the opening of voltage sensitive L-type calcium channels (I_{Ca-L}) and the impulse is transmitted to surrounding cells. B. Coordinated SA nodal depolarization generates an impulse sufficient to open fast sodium channels in surrounding atrial tissue and the impulse spreads along specialized pathways to depolarize the atria and ventricles.

Myocyte Calcium Flow and Contractility

During systole, voltage sensitive slow calcium channels (L-type channels) on the myocyte membrane open in response to cell depolarization allowing calcium to flow down its concentration gradient into the myocyte (Fig. 62–2). Invaginations of the myocyte membrane, known as T-tubules, place L-type calcium channels in close approximation to calcium release channels (ryanodine receptors {RyRs}) on the sarcoplasmic reticulum (SR). The local increase in calcium concentration that follows the opening of a single L-type calcium channel on the cell membrane triggers the opening of the associated RyR channels, resulting in a large release of calcium from the SR, a phenomenon known as calcium-induced calcium release.^{67,224} Myocytes contain tens of thousands of couplons, clusters of L-type calcium channels and RyR channels. The calcium released from one couplon is not sufficient to trigger firing of neighboring couplons.³⁰ Organized myocyte contraction requires synchronized release of calcium from numerous couplons throughout the myocyte. This process depends on membrane depolarization to synchronize opening of L-type channels and subsequent calcium release. This occurs rapidly throughout an extensive network of T-tubules that spans the myocyte.⁸⁶ Following release from the sarcoplasmic reticulum, cytosolic calcium binds to troponin C and allows actin myosin interaction and subsequent myocyte contraction. The strength of contraction is proportional to the amount of calcium release from the SR during depolarization, which depends, in part, on the magnitude of SR calcium stores. Actin–myosin interaction is also modulated by β -adrenergic-mediated troponin phosphorylation, ischemia, intracellular pH, and myofilament stretch.^{9,17,19,209}

FIGURE 62–2. Fluctuations in calcium concentrations couple myocyte depolarization with contraction and myocyte repolarization with relaxation. [1] Depolarization causes voltage sensitive calcium channels to open and calcium to flow down its concentration gradient into the myocyte. [2] This calcium current triggers the opening of calcium release channels in the sarcoplasmic reticulum and calcium pours out of the sarcoplasmic reticulum (SR). The amount of calcium released from the SR is proportional to the initial inward calcium current and to the amount of calcium stored in the SR. [3] At rest, actin–myosin interaction is prevented by troponin. When calcium binds to troponin, this inhibition is removed, actin and myosin slide relative to each other, and the cell contracts. Following contraction, calcium is actively removed from the myocyte to allow relaxation. [4] Most calcium is actively pumped into the SR where it is bound to calsequestrin. Calcium stored in the SR is thus available for release during subsequent depolarizations. The sarcoplasmic calcium ATPase is inhibited by phospholamban (Fig. 62–3). [5] The calcium sodium antiporter couples the flow of three molecules of sodium flow in one direction to that of a single molecule of calcium in the opposite direction. This transporter is passively driven

by electrochemical gradients which usually favor the inward flow of sodium coupled to the extrusion of calcium. Extrusion of calcium is inhibited by high intracellular sodium or extracellular calcium concentrations and by cell depolarization. Under these conditions, the pump may “run in reverse.” [6] Some calcium is actively pumped from the cell by a calcium ATPase. [7] As myocyte calcium concentrations fall, calcium is released from troponin and the myocyte relaxes.

During diastole, several ion pumps actively remove calcium from the cytoplasm (Fig. 62–2). The most important of these are the sarcoplasmic reticulum calcium ATPase that pumps cytosolic calcium into the SR, and the calcium–sodium transporter that exchanges one calcium ion for three sodium ions with the extracellular fluid. The SR calcium ATPase is important for maintaining SR calcium stores and is modulated by β -adrenergic stimulation (see below). When calcium concentrations drop during diastole, calcium dissociates from troponin and relaxation occurs.^{15,17,18,19,187}

β -Adrenergic Receptors and the Heart

β -Adrenergic receptors are divided into β_1 , β_2 , and β_3 subtypes. In the healthy heart, approximately 80% of human cardiac β -adrenergic receptors are β_1 and 20% are β_2 . Human hearts may also contain a small number of β_3 -adrenergic receptors.^{28,60,61,150,177} The relative density of cardiac β_2 -adrenergic receptors increases with heart failure.^{28,200} β_1 -Adrenergic receptors mediate increased inotropy by a well-described pathway involving cyclic AMP and protein kinases (Fig. 62–3). β_1 -Adrenergic receptors are coupled to G_s proteins that activate adenylate cyclase when the receptor is stimulated. This increases intracellular production of cAMP, which binds to and activates protein kinase A and other cAMP-dependent protein kinases.¹²² Protein kinase A, in turn, phosphorylates important myocyte proteins, including phospholamban, the voltage sensitive calcium channels, the calcium release (RyR) channels, and troponin.^{17,28,70,187,204,209} Phosphorylation of the L-type calcium channel increases contractility by increasing the influx of calcium during each cell depolarization triggering greater release of calcium from the sarcoplasmic reticulum.^{169,190,197} Phospholamban inhibits the SR calcium ATPase. Phosphorylation of phospholamban removes this inhibition and increases the activity of the sarcoplasmic calcium ATPase, resulting in increased SR calcium stores and hence enhanced contractility.^{40,204} Improved activity of the SR calcium ATPase will also result in more rapid removal of cytoplasmic calcium during diastole and aid in myocyte relaxation. Phosphorylation of the RyR channels results in more rapid release of calcium from SR stores.^{17,187,209} Troponin phosphorylation facilitates calcium unbinding and thus improves cardiac performance by enhancing myocyte relaxation.^{3,15,123,204} β_1 -Adrenergic receptors increase chronotropy by an incompletely understood mechanism that may involve phosphorylation of SR proteins, resulting in an increased rate of calcium discharge from the SR^{140–142} in addition to direct cAMP interaction with membrane bound pacemaker channels.^{2,26} Although β -adrenergic stimulation acutely improves cardiac function, chronic β -adrenergic stimulation, acting through β_1 -adrenergic receptors, results in a number of detrimental effects, including calcium overload, increased risk of dysrhythmias, impaired excitation-contraction coupling, and myocyte apoptosis.^{17,28,230}

FIGURE 62–3. β_1 -adrenergic agonists are positive inotropes by virtue of their ability to activate protein kinase A (PKA). [1] β_1 -adrenergic receptors are coupled to G_s proteins, which activate adenyl cyclase when catecholamines bind to the

receptor. This causes increased formation of cAMP from ATP. [2] Increased cAMP concentrations activate PKA, which mediates the ultimate effects of β -adrenergic receptor stimulation by phosphorylating key intracellular proteins. [3] Phosphorylation of phospholamban disinhibits the sarcoplasmic reticulum (SR) calcium ATPase resulting in increased SR calcium stores available for release during subsequent depolarizations and phosphorylation of SR calcium release channels enhances calcium release from SR stores during contraction. [4] Phosphorylation of voltage sensitive calcium channels increases calcium influx through these channels during systole. [5] Troponin phosphorylation improves cardiac performance by facilitating calcium unbinding during diastole. β_2 Receptors are also coupled to G_s proteins and mediate positive inotropy through a cAMP mechanism. Increased cAMP directly increases heart rate (Fig. 62–1).

Cardiac β_2 -adrenergic receptors are dually linked to both excitatory G_s proteins and inhibitory G_i proteins.^{101,175,231} Under normal conditions, the G_s pathway predominates in human cardiac β_2 -adrenergic receptors and β_2 -adrenergic stimulation increases contractility, relaxation, and chronotropy through the protein kinase A pathway described above. However, in the failing heart, the inhibitory G_i protein pathway becomes dominant and β_2 -adrenergic stimulation inhibits cardiac function.^{28,73,187} Chronic β_2 -adrenergic stimulation may prevent myocyte apoptosis.²³⁰

Noncardiac Effects of β -Adrenergic Receptor Activation

β -Adrenergic agonists have important noncardiac effects. β -Adrenergic receptors mediate smooth muscle relaxation in several organs. Relaxation of arteriolar smooth muscle predominately by β_2 -adrenergic stimulation reduces peripheral vascular resistance and decreases blood pressure. This counteracts α -adrenergic-mediated arteriolar constriction. In the lungs, β_2 -adrenergic receptors mediate bronchodilation. Unfortunately, chronic β -adrenergic stimulation may cause adverse pulmonary effects, including mucous cell proliferation, hyperreactive airways, and inflammation.³⁷ Third-trimester uterine tone and contractions are inhibited by β_2 -adrenergic agonists, and gut motility is decreased by both β_1 - and β_2 -adrenergic stimulation. Chronic, high-dose β_2 -adrenergic stimulation causes skeletal muscle hypertrophy.¹⁰⁴

β -Adrenergic receptors play a role in the immune system. Mast cell degranulation is inhibited by β_2 -adrenergic stimulation, explaining the role of epinephrine in aborting and treating severe allergic reactions. Polymorphonuclear leukocytes demarginate in response to β -adrenergic stimulation, resulting in the increased white blood cell counts with catecholamine infusions or with increased endogenous release of epinephrine that occurs with pain or physiologic stress.

β -Adrenergic agonists also have important metabolic effects. Insulin secretion is increased by β_2 -adrenergic receptor stimulation. Despite increased insulin concentrations, the net effect of β_2 -adrenergic receptor stimulation is to increase glucose due to increased skeletal muscle glycogenolysis and hepatic gluconeogenesis and glycogenolysis. β_2 -Adrenergic receptors also cause glucagon secretion from pancreatic α cells.¹¹⁰ β -Adrenergic agonists act at fat cells to cause lipolysis and thermogenesis. Stimulation of adipocyte β -adrenergic receptors results in breakdown of triglycerides and release of free fatty acids. Skeletal muscle potassium uptake is increased by β_2 -adrenergic stimulation resulting in hypokalemia, explaining the role of β_2 -adrenergic agonists in the treatment of hyperkalemia. Finally, renin secretion is increased by β_1 -adrenergic stimulation, resulting in increased blood pressure.²²³

Effects of β -Adrenergic Antagonists

β -Adrenergic antagonists competitively antagonize the effects of catecholamines at β -adrenergic receptors and blunt the chronotropic and inotropic response to catecholamines. Bradycardia and hypotension may be severe in patients who take additional medications that impair cardiac conduction or contractility or in those with underlying cardiac or medical conditions that make them reliant on sympathetic stimulation. In addition to slowing the rate of SA node discharge, β -adrenergic antagonists inhibit ectopic pacemakers and slow conduction through atrial and AV nodal tissue. β -Adrenergic antagonists block the detrimental effects of chronic adrenergic overstimulation and have become standard of care for patients with all stages of compensated chronic heart failure, including patients with stable NYHA (New York Heart Association) class III or IV disease.^{1,66,226} β -Adrenergic blockade may exacerbate symptoms in patients with decompensated congestive heart failure but, in the absence of cardiogenic shock or symptomatic bradycardia, β -adrenergic antagonists should not be routinely discontinued in heart failure patients admitted to hospital.²²⁹ β -Adrenergic antagonists prevent adverse cardiac events in patients with recent myocardial infarctions but may be ineffective in patients with prior myocardial infarction, stable coronary artery disease, or risk factors for coronary artery disease.¹³

The antihypertensive effect of β -adrenergic antagonists is counteracted by a reflex increase in peripheral vascular resistance. This effect is augmented by the β_2 -adrenergic antagonism of nonselective β -adrenergic antagonists. By causing increased peripheral vascular resistance, β_2 -adrenergic antagonists may rarely worsen peripheral vascular disease.

Patients with reactive airways disease may suffer severe bronchospasm after using β -adrenergic antagonists due to loss of β_2 -adrenergic-mediated bronchodilation. Catecholamines inhibit mast cell degranulation through a β_2 -adrenergic

mechanism. Interference with this may predispose to life-threatening effects following anaphylactic reactions in atopic individuals.⁸⁹ β_2 -Adrenergic antagonists impair the ability to recover from hypoglycemia and may mask the sympathetic discharge that serves to warn of hypoglycemia. This combination of effects is dangerous for patients with diabetes at risk for hypoglycemic episodes.²²³

β_2 -Adrenergic antagonism inhibits catecholamine-mediated potassium uptake at skeletal muscle. This may cause slight elevations in serum potassium especially after exercise. Although β_2 -adrenergic stimulation augments insulin release, β -adrenergic antagonists seldom lower insulin concentrations and may actually cause hypoglycemia by interference with glycogenolysis and gluconeogenesis. These effects are important in patients with diabetes at risk for hypoglycemia. β -Adrenergic antagonists also alter lipid metabolism. Although the release of free fatty acids from adipose tissue is inhibited, patients taking nonselective β -adrenergic antagonists typically have increased plasma concentrations of triglycerides and decreases in high-density lipoproteins.²²³

PHARMACOKINETICS

The pharmacokinetic properties of the β -adrenergic antagonists depend in large part on their lipophilicity. Propranolol is the most lipid soluble of the β -adrenergic antagonists and atenolol is the most water soluble. The oral bioavailability of the β -adrenergic antagonists ranges from approximately 25% for propranolol to almost 100% for pindolol and penbutolol.

The highly lipid-soluble drugs cross lipid membranes rapidly and concentrate in adipose tissue. These properties allow rapid entry into the central nervous system (CNS), and typically result in large volumes of distribution. In contrast, highly water-soluble drugs, cross lipid membranes slowly, distribute in total body water, and tend to have less CNS toxicity. Volumes of distribution range from about 1 L/kg for atenolol to more than 100 L/kg for carvedilol.

The highly lipid soluble β -adrenergic antagonists are highly protein bound and poorly excreted by the kidneys. They require hepatic biotransformation before they can be eliminated and accumulate in patients with liver failure. By contrast, the water-soluble β -adrenergic antagonists tend to be slowly absorbed, poorly protein bound, and renally eliminated. They accumulate in patients with kidney failure. Esmolol, although water-soluble, is rapidly metabolized by red blood cell esterases and does not accumulate in patients with kidney failure. The half-life of esmolol is about 8 minutes. Half-lives of the other β -adrenergic antagonists range from about 2 hours for oxprenolol to as much as 32 hours for nebivolol. The β -adrenergic antagonists also differ in their β_1 -adrenergic selectivity, intrinsic sympathomimetic activity, and vasodilatory properties (Table 62–1).^{157,166,170,206,223}

β_1 Selectivity (Acebutolol, Atenolol, Betaxolol, Bisoprolol, Celiprolol, Esmolol, Metoprolol, Nebivolol)

β_1 -Selective antagonists may avoid some of the adverse effects of the non-selective antagonists. Short-term use of β_1 -adrenergic selective antagonists appears to be safe in patients with mild to moderately severe reactive airways.¹⁸¹ These drugs may be safer for patients with diabetes mellitus or peripheral vascular disease and may be more effective antihypertensives. Their β_1 -adrenergic selectivity, however, is incomplete, and adverse reactions secondary to β_2 -adrenergic antagonism may occur with therapeutic dosage as well as in overdose.^{124,223}

Membrane Stabilizing Effects (Acebutolol, Betaxolol, Carvedilol, Oxprenolol, Propranolol)

β -Adrenergic antagonists that inhibit fast sodium channels (also known as type I antidysrhythmic activity) are said to possess membrane-stabilizing activity. No significant membrane stabilization occurs with therapeutic use of β -adrenergic antagonists, but this property can contribute to toxicity in overdose.

Intrinsic Sympathomimetic Activity (Acebutolol, Carteolol, Oxprenolol, Penbutolol, Pindolol)

These medications act as partial agonists at β -adrenergic receptors and are said to have intrinsic sympathomimetic activity (ISA). This property is unrelated to β_1 -adrenergic selectivity. These drugs may avoid the dramatic decrease in resting heart rate that occurs with β -adrenergic antagonism in susceptible patients, but their clinical benefit is not demonstrated in controlled trials.^{50,57}

Potassium Channel Blockade (Acebutolol, Sotalol)

Sotalol is a nonselective β -adrenergic antagonist with low lipophilicity, no membrane stabilizing effect, and no ISA.

Sotalol is unique because of its ability to block the delayed rectifier potassium current responsible for repolarization. This prolongs the action potential duration and is manifested on the electrocardiogram (ECG) by a prolonged QT interval.⁸¹ The prolonged QT interval predisposes to torsade de pointes and ventricular dysrhythmias may complicate the therapeutic use of sotalol.¹⁰⁸ In patients taking sotalol therapeutically, torsade de pointes is most common in those who have kidney failure, use other drugs that prolong the QT interval, or have predisposing factors for QT prolongation such as hypokalemia, hypomagnesemia, bradycardia, or congenital QT prolongation.^{38,81} Some authors suggest that QT dispersion is a better predictor of sotalol induced torsade de pointes than QT prolongation alone (Chap. 17). A difference between the longest and shortest QT interval on 12-lead ECG of more than 100 milliseconds indicates an increased risk of torsade de pointes.³⁸ Acebutolol also prolongs the QT interval presumably secondary to blockade of outward potassium channels.¹²⁵

Vasodilation (Betaxolol, Bucindolol, Carteolol, Carvedilol, Celiprolol, Labetalol, Nebivolol)

Labetalol and the newer “third-generation” β -adrenergic antagonists (betaxolol, bucindolol, carteolol, carvedilol, celiprolol, nebivolol) are also vasodilators. Labetalol and carvedilol are nonselective β -adrenergic antagonists that also possess α -adrenergic antagonist activity. Nebivolol is a selective β_1 -adrenergic antagonist that causes vasodilation by release of nitric oxide.¹⁴³ Bucindolol, carteolol, and celiprolol vasodilate because they are agonists at β_2 -adrenergic receptors. Celiprolol and carteolol also vasodilate because of nitric oxide mediated effects. Bucindolol and celiprolol are not FDA approved. Carteolol is currently available as an ocular preparation. Betaxolol and carvedilol also have calcium channel blocking properties that result in vasodilation (Table 62–1). β -Adrenergic antagonists with vasodilating properties may be particularly beneficial for patients with congestive heart failure.¹⁶⁴ These drugs may also have a role in managing patients with coronary artery disease or peripheral vascular disease. Those drugs with β_2 -adrenergic agonist activity may prove useful for patients with reactive airways.

β -Adrenergic antagonists should not be given without appropriate α -adrenergic blockade in situations of catecholamine excess such as pheochromocytoma. In these conditions, β_2 -adrenergic-mediated vasodilation is essential to counteract α -adrenergic-mediated vasoconstriction. β -Adrenergic antagonists would result in “unopposed α ” adrenergic effect causing dangerous increases in vascular resistance. Even agents with combined α - and β -adrenergic antagonist properties can cause this problem. Labetalol, for example, is five to ten-fold more potent as a β -adrenergic antagonist than as an α -adrenergic antagonist. Theoretically, xenobiotics with β_2 -adrenergic agonist properties may avoid the “unopposed α ” effect, but their use in this situation has not yet been investigated.^{48,63,143,210,223}

Other Preparations (Ophthalmic Preparations, Sustained Release, Combined Products)

Therapeutic use of ophthalmic solutions containing β -adrenergic antagonists may cause systemic adverse effects such as bradycardia, high-grade AV block, heart failure, and bronchospasm.^{24,56,151,189,191,216,223}

An extended-release tablet containing a combination of the calcium channel blocker, felodipine, and metoprolol has been studied as an antihypertensive medication.^{69,85} This medication (Logimax, AstraZeneca) is marketed in more than 35 countries worldwide but is not available in the United States or Canada. Another combined β -adrenergic and calcium channel antagonist containing atenolol and nifedipine (Nif-Ten, AstraZeneca) is also used as an antihypertensive.⁴⁵

PATHOPHYSIOLOGY

Most of the toxicity of β -adrenergic antagonists is due to their ability to competitively antagonize the action of catecholamines at cardiac β -adrenergic receptors. The peripheral vascular effects of β -adrenergic antagonism are less prominent in overdose. β -Adrenergic antagonists also appear to have toxic effects independent of their action at catecholamine receptors. In catecholamine depleted, spontaneously beating isolated rat hearts, propranolol, timolol and sotalol all decreased heart rate and contractility.⁴² Surprisingly, these effects were similar in catecholamine depleted and nondepleted hearts.¹¹⁴ A membrane depressant effect likely contributes to the cardiac depressant effects of propranolol but not to that of timolol or sotalol. It may be concluded that β -adrenergic antagonists cause myocardial depression at least in part by an action independent of catecholamine antagonism or membrane depressant activity.¹¹⁴ This effect may be mediated by interference with calcium handling in the sarcoplasmic reticulum.

Other investigators studied the role of extracellular ions and cardiac membrane potential in modulating β -adrenergic antagonist toxicity. β -Adrenergic antagonists interfere with calcium uptake into intracellular organelles. This interference with cytosolic calcium handling may stimulate calcium sensitive outward potassium channels and result in myocyte hyperpolarization and subsequent refractory bradycardia. Lowering extracellular potassium or raising extracellular sodium

concentrations was conjectured to counteract this effect and, in fact, partially reversed propranolol and atenolol toxicity in isolated rat hearts.⁹⁷ In another series of experiments with isolated rat hearts, calcium improved the function of rat hearts poisoned with β -adrenergic antagonists. This may have been due to a nonspecific positive inotropic action of calcium.¹¹⁴

Although cardiovascular effects are most prominent in overdose, β -adrenergic antagonists also cause respiratory depression.¹¹⁵ This effect is centrally mediated and appears to be an important cause of death in spontaneously breathing animal models of β -adrenergic antagonism toxicity.¹¹⁶ There is evidence that propranolol is concentrated in synaptic vessels and may impair synaptic function by inhibition of membrane ion pumps, including the sodium-potassium ATPase, the calcium ATPase, and the magnesium ATPase. These actions may explain some of the CNS effects noted in propranolol overdose.⁶⁴

CLINICAL MANIFESTATIONS

Symptoms of toxicity generally occur within hours after β -adrenergic antagonist overdose. Propranolol overdose, in particular, may be complicated by the rapid development of hypoglycemia, seizures, coma, and dysrhythmias. In a retrospective review of published reports of adult β -adrenergic antagonist overdose there were 39 symptomatic patients with well documented times from ingestion to symptom onset. Only one patient had ingested a sustained release product. Thirty-one patients were symptomatic at 2 hours, all but one developed symptoms at 4 hours, and everyone developed symptoms within the first 6 hours. The authors conclude that there have been no well documented reports of immediate release β -adrenergic antagonist overdose resulting in toxicity delayed more than 6 hours after ingestion.¹²⁶ The authors of an Australian series also noted that, in their 58 patients with β -adrenergic antagonist overdose, all major symptoms began within 6 hours of ingestion.¹⁶⁷ These observations do not apply to sotalol, which is well known to cause delayed toxicity in overdose, or to sustained-release preparations.

Isolated β -adrenergic antagonist overdose in healthy people is often benign. In several series, one-third or more of patients reporting a β -adrenergic overdose remained asymptomatic.^{46,51,127,206} This is partially explained by the fact that β -adrenergic antagonism is often well tolerated in healthy persons who do not rely on sympathetic stimulation to maintain cardiac output. In particular, unintentional ingestions in children rarely result in significant toxicity.¹⁶ In fact, a review of published cases found a few reports of hypoglycemia but no deaths or serious cardiovascular morbidity following β -adrenergic antagonist ingestion in children younger than 6 years of age.¹³⁵

β -Adrenergic antagonists severely impair the ability of the heart to respond to peripheral vasodilation, bradycardia, or decreased contractility caused by other xenobiotics. Therefore even relatively benign vasoactive xenobiotics may cause catastrophic toxicity when coingested with β -adrenergic antagonists.⁵⁸ According to one author, the most important predictor of toxicity in β -adrenergic antagonist overdose is likely to be the presence of a cardioactive coingestant.¹²⁹ Isolated β -adrenergic antagonist overdose is most likely to cause symptoms in persons with congestive heart failure, sick sinus syndrome, or impaired AV conduction who rely on sympathetic stimulation to maintain heart rate or cardiac output. Nevertheless, severe toxicity and death may still occur in healthy persons who have ingested β -adrenergic antagonists alone.^{54,167,198} This may be explained by an increased susceptibility of certain persons to β -adrenergic antagonism or by special properties that increase the toxicity of certain β -adrenergic antagonists (see below). In patients without a coingestant, toxicity is most likely to occur in those who ingest a β -adrenergic antagonist with membrane stabilizing activity.¹²⁹

Patients with symptomatic β -adrenergic antagonist overdose will most often be hypotensive and bradycardic. Decreased SA node function results in sinus bradycardia, sinus pauses, or sinus arrest. Impaired atrioventricular conduction manifested as prolonged PR interval or high-grade AV block occurs rarely. Prolonged QRS and QT intervals may occur and severe poisonings may result in asystole. Congestive heart failure often complicates β -adrenergic antagonist overdose. Delirium, coma, and seizures occur most commonly in the setting of severe hypotension but may also occur with normal blood pressure, especially with exposure to the more lipophilic xenobiotics such as propranolol.^{54,167} Respiratory depression and apnea may have an additional role in toxicity.⁶ In a review of reported cases, 18% of patients with propranolol toxicity and 6% of those with atenolol toxicity had a respiratory rate fewer than 12 breaths/min.¹⁶⁷ Respiratory depression following β -adrenergic antagonist overdose typically occurs in patients who are hypotensive and comatose but is reported in awake patients.¹⁵³ Hypoglycemia may complicate β -adrenergic antagonist poisoning in children^{77,135} but is uncommon in acutely poisoned adults. In a series of 15 cases of β -adrenergic antagonist overdose, none of the 13 adults were hypoglycemic whereas both of the two children had symptomatic hypoglycemia.⁵⁴ Bronchospasm is relatively uncommon following β -adrenergic antagonist overdose and appears to occur only in susceptible patients. In the series mentioned above, only two of the 15 patients developed bronchospasm⁵⁴ and in a recent review of 39 cases of symptomatic adults with β -adrenergic antagonist overdose, only one patient developed bronchospasm.¹²⁶ Clinical use of β -adrenergic antagonists slightly increases serum potassium¹³⁶; however, significant hyperkalemia is rare.

β₁ Selectivity (Acebutolol, Atenolol, Betaxolol, Bisoprolol, Esmolol, Metoprolol, Nebivolol)

In overdose, cardioselectivity is largely lost and deaths due to the β₁-adrenergic selective agents including acebutolol,⁷⁵ atenolol,¹³³ betaxolol,²⁰ and metoprolol^{172,198} are reported. There have been single reports of minor toxicity following overdose with bisoprolol²¹² and nebivolol.⁷⁴

Membrane-Stabilizing Effects (Acebutolol, Betaxolol, Carvedilol, Oxprenolol, Propranolol)

Propranolol possesses the most membrane stabilizing activity of this class and propranolol poisoning is characterized by coma, seizures, hypotension, bradycardia, impaired atrioventricular conduction, and widened QRS interval. A Brugada-pattern on ECG may occur following propranolol overdose (Chap. 16).¹⁶⁸ Ventricular tachydysrhythmias may also occur.^{4,133} Hypotension may be out of proportion to bradycardia and deaths from propranolol overdose are well reported.^{54,75,133} Acebutolol, betaxolol and oxprenolol also possess significant membrane stabilizing activity and have caused fatalities when taken in overdose.^{20,75,100,157,165}

Lipid Solubility

In overdose, the more lipophilic β-adrenergic antagonists may cause delirium, coma, and seizures even in the absence of hypotension.^{54,167} Atenolol, the least lipid soluble of β-adrenergic antagonists, appears to be one of the safer β-adrenergic antagonists when taken in overdose.⁷⁵ In fact, in one series of β-adrenergic antagonist overdoses, none of the 18 patients with atenolol overdose had seizures compared with eight out of 28 patients with propranolol overdose.¹⁶⁷ Nevertheless, atenolol overdose may result in severe toxicity and cardiovascular death.^{133,161,202}

Intrinsic Sympathomimetic Activity (Acebutolol, Carteolol, Oxprenolol, Penbutolol, Pindolol)

There is little experience with overdose of these agents, but ISA would theoretically make these drugs safer than the other β-adrenergic antagonists. Sympathetic stimulation with mild tachycardia or hypertension often predominates in pindolol overdose, and this class of medications appears to be relatively safe in overdose.^{54,109,166} In addition to ISA, acebutolol and oxprenolol have significant membrane-stabilizing activity, making them dangerous in overdose, and deaths due to acute toxicity from these β-adrenergic antagonists are reported.^{54,75,125,165} Overdose with carteolol or penbutolol has not been reported.

Potassium Channel Blockade (Acebutolol, Sotalol)

In six patients with sotalol overdose, the average QT interval was 172% of normal and five patients had ventricular dysrhythmias, including multifocal ventricular extrasystoles, ventricular tachycardia, and ventricular fibrillation.¹⁵⁶ Sotalol overdose may also be complicated by hypotension, bradycardia, and asystole,^{5,156} and fatalities are well documented.^{152,160}

Sotalol overdose may cause delayed and prolonged toxicity although ECG changes appear to occur early. In a series of six patients with sotalol overdose, all had prolonged QT interval noted on the initial ECG taken 30 minutes to 4.5 hours after ingestion. It is not clear whether these patients were taking sotalol therapeutically prior to the overdose so it is possible that the prolonged QT on the initial ECG was present prior to the overdose. The greatest QT prolongation occurred 4 to 15 hours after ingestion, and the risk of ventricular dysrhythmias was highest between 4 and 20 hours. All four patients who developed ventricular tachycardia did so after 4 hours, and in two patients ventricular dysrhythmias first occurred 9 hours after ingestion. One patient continued to have ventricular dysrhythmias at 48 hours, and abnormally prolonged QT intervals were noted as long as 100 hours after ingestion. In this series the average sotalol half-life was 13 hours, and the average time until normalization of the QT interval was 82 hours.¹⁵⁶ Acebutolol-induced QT interval prolongation may partially explain the ventricular tachydysrhythmias that occur with severe acebutolol toxicity.^{44,125,133}

Vasodilation (Betaxolol, Bucindolol, Carteolol, Carvedilol, Celiprolol, Labetolol, Nebivolol)

The vasodilatory properties of these drugs would theoretically act in synergy with β-adrenergic antagonism to increase toxicity. Conversely, the low membrane-stabilizing effect of these drugs may make them relatively safe in overdose. Betaxolol is the sole drug in this class with membrane stabilizing properties. Overdose with labetalol appears to be similar to that of other β-adrenergic antagonists with hypotension and bradycardia as prominent features.^{103,105,194} Experience with

overdose of the newer vasodilating β -adrenergic antagonists is limited. Similar to conventional β -adrenergic antagonists, carvedilol overdose causes hypotension and bradycardia.^{23,68,205} In a case report from Germany, nebivolol overdose was complicated by bradycardia, lethargy, and hypoglycemia. The patient received standard treatment and had a benign outcome.⁷⁴ Another patient became hypotensive and bradycardic and then experienced cardiac arrest following nebivolol overdose. That person was successfully resuscitated with lipid emulsion and high-dose insulin.²⁰¹ Severe toxicity and death have occurred following betaxolol^{20,21} and celiprolol¹⁷⁶ poisoning. Overdoses with bucindolol or carteolol have not been reported.

Other Preparations (Ophthalmic Preparations, Sustained Release, Combined Products)

There is very little published experience with overdoses of the sustained release β -adrenergic antagonists, but it is reasonable to expect that overdose with these agents will result in both a delayed onset and prolonged duration of toxicity. Acute overdose of ophthalmic β -adrenergic antagonists has not been reported. Patients who take mixed overdoses with calcium channel antagonists and β -adrenergic antagonists are difficult to manage because of synergistic toxicity.^{180,188,195} Overdoses with combined β -adrenergic antagonist and calcium channel blocker preparations such as felodipine and metoprolol or atenolol and nifedipine have not been reported, but these combinations would be expected to be quite dangerous in overdose.

DIAGNOSTIC TESTING

All patients with an intentional overdose of a β -adrenergic antagonist should have a 12-lead ECG and continuous cardiac monitoring. Serum glucose should be measured regardless of mental status because β -adrenergic antagonists can cause hypoglycemia. A chest radiograph and assessment of oxygen saturation should be obtained if the patient is at risk for or suffering symptoms of congestive heart failure. For patients with bradycardia of uncertain etiology, measurement of thyroid function, potassium, kidney function, cardiac enzymes, and digoxin concentration may prove helpful. Serum concentrations of β -adrenergic antagonists are not readily available for routine clinical use but may prove helpful in making a retrospective diagnosis in selected cases. Lactate concentrations may be elevated in patients with β -adrenergic antagonist poisoning but are poor predictors of survival.¹⁴⁷

MANAGEMENT

Airway and ventilation should be maintained with endotracheal intubation if necessary. Because laryngoscopy may induce a vagal response, it is reasonable to give atropine prior to intubation of the bradycardic patient. This is particularly true for children who are more susceptible to this complication. The initial treatment of bradycardia and hypotension consists of atropine and intravenous fluids. These measures will likely be insufficient in patients with severe toxicity but may suffice in patients with mild poisoning or other etiologies for bradycardia.

Gastrointestinal decontamination is warranted for all persons who have ingested significant amounts of a β -adrenergic antagonist. Induction of emesis is contraindicated because of the potential for catastrophic deterioration of mental status and vital signs in these patients, and since vomiting increases vagal stimulation and may worsen bradycardia.¹⁹⁶ Orogastric lavage is recommended for patients with significant effects such as seizures, hypotension, or bradycardia if the patient presents in a time frame when the drug is still expected to be in the stomach. Orogastric lavage is also recommended for all patients who present shortly after ingestion of large (gram amount) ingestions of propranolol or one of the other more toxic β -adrenergic antagonists (ie, acebutolol, betaxolol, metoprolol, oxprenolol, sotalol). Orogastric lavage causes vagal stimulation and carries the risk of worsening bradycardia so it is reasonable to pretreat patients with standard doses of atropine. We recommend activated charcoal alone for persons with minor symptoms following an overdose with one of the more water-soluble β -adrenergic antagonists who present later than one hour following ingestion. Whole bowel irrigation with polyethylene glycol should be considered in patients who have ingested sustained release preparations (Antidotes in Depth: A2).

Seizures or coma associated with cardiovascular collapse is treated by attempting to restore circulation. Seizures in the patient with relatively normal vital signs should be treated with benzodiazepines followed by barbiturates if benzodiazepines fail. Refractory seizures are rare in β -adrenergic antagonist overdose.

Specific Management

Patients who fail to respond to atropine and fluids require management with the inotropics discussed below (Fig. 62–4). When time permits, it is preferable to introduce new medications sequentially so that the effects of each may be assessed. We recommend glucagon followed by calcium, and high-dose insulin euglycemia therapy. In the critically ill patient, there

may not be enough time for this approach and multiple treatments may be started simultaneously. If these therapies fail, we suggest starting a catecholamine pressor and phosphodiesterase inhibitors. Advanced hemodynamic monitoring, when available, is advisable to guide therapy for all patients receiving catecholamine pressors or phosphodiesterase inhibitors. Lipid emulsion therapy should be given to patients with severe toxicity or cardiac arrest. Mechanical life support with intra-aortic balloon pump or extracorporeal circulation may be lifesaving when medical management fails and is most effective when started early.

FIGURE 62–4. Positive inotropes improve cardiac function by a number of mechanisms, which usually result in increased intracellular calcium. Xenobiotics that [1] increase cAMP: Glucagon receptors and β -adrenergic receptors are coupled to G_s proteins so that receptor binding increases cAMP by activation of adenylyl cyclase. Phosphodiesterase inhibitors increase cAMP by inhibiting its breakdown. [2] increase calcium influx: Calcium salts increase calcium influx through L-type calcium channels by a direct mass effect. [3] inhibit extrusion of calcium via the sodium-calcium exchange pump: Those that increase intracellular sodium such as digoxin and sodium channel agonists (eg, aconitine) and those such as 4-aminopyridine that prolong the action potential duration alter the electrochemical gradients in a way that hinders the extrusion of calcium. [4] increase the sensitivity of the contractile elements to calcium: Angiotensin II and endothelin do this by inducing an intracellular alkalosis. The calcium sensitizers, levosimendan and pimobendan are used to treat heart failure in some countries.

Glucagon

Cardiac glucagon receptors,²²⁰ like β -adrenergic receptors, are coupled to G_s proteins. Glucagon binding increases adenylyl cyclase activity independent of β -adrenergic receptor binding.²²⁷ The inotropic effect of glucagon is enhanced by its ability to inhibit phosphodiesterase and thereby prevent cAMP breakdown.¹⁴⁹

There are no controlled trials of glucagon in humans with β -adrenergic antagonist poisoning.^{12,25} Nevertheless, with more than 30 years of clinical use,^{107,217} glucagon is still recognized as a useful treatment of choice for severe β -adrenergic antagonist toxicity.^{96,163,206,222} This is supported by animal models,^{62,106,132} and a case series suggesting that glucagon is also effective in correcting symptomatic bradycardia and hypotension secondary to therapeutic β -adrenergic antagonist use.¹³⁴ Glucagon is a vasodilator, and in animal models of propranolol poisoning it is more effective in restoring contractility, cardiac output, and heart rate than in restoring blood pressure.^{12,132}

The initial adult dose of glucagon for β -adrenergic antagonist toxicity is 3 to 5 mg given slowly over 1 to 2 minutes. The initial pediatric dose is 50 μ g/kg. If there is no response to the initial dose, higher doses up to a total of 10 mg may be

used. Once a response occurs, a glucagon infusion is started. Most authors recommend using an infusion of 2 to 5 mg/h, although many authorities recommend glucagon infusions as high as 10 mg/h. We suggest that the glucagon infusion be started at the “response dose” per hour. Thus, for example, if the patient receives 7 mg of glucagon before a response occurs, the glucagon infusion should be started at 7 mg/h. When a full 10 mg dose of glucagon fails to restore blood pressure and heart rate and the diagnosis of β -adrenergic antagonist toxicity is probable, we still recommend starting an infusion of glucagon at 10 mg/h as glucagon will have synergistic effects with subsequent antidotes. Glucagon may cause vomiting with risk of aspiration. Other adverse events of glucagon in this setting include hyperglycemia and mild hypocalcemia⁸⁷ and these should be treated appropriately if they develop. Patients also develop rapid tachyphylaxis to glucagon, and the need for increasing doses and additional therapies should be expected, even when patients initially respond (Antidotes in Depth: A18).

Calcium

Calcium salts effectively treat hypotension but not heart rate in animal models of β -adrenergic antagonist toxicity.^{114,128} Calcium chloride successfully reverses hypotension in patients with β -adrenergic antagonist overdose^{27,161} and in combined calcium channel blocker and β -adrenergic antagonist toxicity.⁷⁶ The adult starting dose of calcium gluconate is 3 g of the 10% solution given intravenously. We recommend using up to 9 g of calcium gluconate if needed. The initial dose of calcium gluconate in children is 60 mg/kg up to 3 g. This may be repeated up to a total of 180 mg/kg (Antidotes in Depth: A29).

Insulin and Glucose

High-dose insulin, euglycemia therapy improves cardiac function following cardiac surgery⁶⁵ and survival following myocardial infarction.^{49,137-139} There is evidence that high-dose insulin combined with sufficient glucose to maintain euglycemia is beneficial in β -adrenergic antagonist poisoning. In a canine model of propranolol toxicity, all six animals treated with insulin and glucose survived compared with four out of six in the glucagon group, one of six in the epinephrine group, and no survivors in the sham treatment group.⁹⁹ Insulin plus glucose was markedly more effective than vasopressin plus epinephrine in a porcine model of propranolol toxicity. In that experiment, all five animals in the insulin group survived the 4-hour protocol and all five in the vasopressin plus epinephrine group died within 90 minutes.⁸² In a rabbit model of severe propranolol toxicity, high-dose insulin was more effective than lipid emulsion in restoring blood pressure and heart rate, but there was no difference in survival.⁷¹ Clinical experience with high-dose insulin for β -adrenergic antagonist poisoning is increasing but still limited to case reports and case series.⁴⁷ Improvements in heart rate and blood pressure following high-dose insulin are reported in patients with isolated overdoses of metoprolol, nebivolol, and propranolol.^{84,158,201} High-dose insulin was also effective in combined poisoning with β -adrenergic antagonists and calcium channel blockers.^{84,228}

High-dose insulin is simple to use, safe (with appropriate monitoring of glucose and potassium), and does not require invasive monitoring. For these reasons, we recommend using high-dose insulin and glucose infusions for patients with β -adrenergic antagonist toxicity who have not responded to fluids, atropine, and glucagon. Although the dose of insulin is not definitively established, therapy typically begins with a bolus of 1 unit/kg of regular human insulin along with 0.5 g/kg of dextrose. If blood glucose is greater than 300 mg/dL (16.7 mmol/L), the dextrose bolus is not necessary. An infusion of regular insulin should follow the bolus starting at 1 unit/kg/h. A continuous dextrose infusion, beginning at 0.5 g/kg/h should also be started. Glucose should be monitored every 15 to 30 minutes until stable and then every 1 to 2 hours and titrated to maintain the blood glucose between 100 and 250 mg/dL. Cardiac function should also be reassessed every 10 to 15 minutes, and if it remains depressed, the insulin infusion can be increased up to 10 units/kg/h as required (rarely higher). The goal of therapy includes improved organ perfusion with improvements in cardiac output, mental status, urine output, and acid-base abnormalities. The response to insulin is typically delayed for 15 to 60 minutes so it will usually be necessary to start a catecholamine infusion before the full effects of insulin are apparent. It is important to continue monitoring glucose and electrolytes for several hours after insulin is discontinued (Antidotes in Depth: A17).

Catecholamines

Patients who do not respond to the preceding therapies usually require a catecholamine infusion. The choice of catecholamine is somewhat controversial. Theoretically, the pure β -adrenergic agonist isoproterenol would seem to be the ideal agent because it can overcome β -adrenergic blockade without causing any α -adrenergic effects. Unfortunately, this therapy has several potential drawbacks, which limit its efficacy. In the presence of β -adrenergic antagonism, extraordinarily high doses of isoproterenol and other catecholamines are frequently required.^{36,165,171,206,215} Individual case reports document isoproterenol infusions as high as 800 μ g/min.¹⁶⁶ At these high doses, the β_2 -adrenergic effects of isoproterenol cause peripheral vasodilation and may actually lower blood pressure.¹⁷¹ Nevertheless, in some animal models, isoproterenol is the most effective catecholamine and is even more effective than glucagon in reversing β -

adrenergic antagonist toxicity.^{203,219} However, clinical experience has not shown this to be the case. In a review of reported cases, glucagon increased heart rate 67% of the time and blood pressure 50% of the time. In contrast, isoproterenol was effective in increasing heart rate only 11% of the time and blood pressure only 22% of the time. Epinephrine was more effective than isoproterenol.²²² The selective β_1 -adrenergic agonist prenalterol may avoid some of the problems associated with isoproterenol and was used successfully to treat β -adrenergic antagonist overdose.^{52,109} Prenalterol would be expected to be especially effective following overdose of the cardioselective β -adrenergic antagonists.⁵² Prenalterol is not FDA approved and prenalterol therapy is limited as its relatively long half-life (~ 2 hours) makes titration difficult.¹⁷³ Dobutamine is a β_1 -adrenergic agonist with relatively little effect on vascular resistance that may be useful in this setting. However, experience is limited and dobutamine is not always effective in patients with β -adrenergic antagonist overdose.^{165,193} In the setting of β -adrenergic antagonism, catecholamines with substantial α -adrenergic agonist properties may increase peripheral vascular resistance without improving contractility, resulting in acute cardiac failure. Severe hypertension due to lack of β_2 -adrenergic-mediated vasodilation is another potential adverse reaction from this so-called “unopposed α -adrenergic” effect.⁵⁹ Because of these potential problems, we recommend that catecholamine use be guided by hemodynamic monitoring using noninvasive techniques such as bioimpedance or echocardiographic monitoring or direct invasive measures of determining cardiac performance. Catecholamine infusions should be started at the usual rates and then increased rapidly until a clinical effect is obtained. If advanced monitoring is impossible and the diagnosis of β -adrenergic antagonist overdose is fairly certain, it is reasonable to begin an isoproterenol or epinephrine infusion with careful monitoring of the patient’s blood pressure and clinical status. The infusion should be stopped immediately if the patient becomes more hypotensive or develops congestive heart failure.

Lipid Emulsion

Lipid emulsion is a promising antidote that has a role in selected cases of severe β -adrenergic antagonist overdose. Intravenous administration of lipid emulsion is hypothesized to reduce the toxicity of lipid-soluble xenobiotics by lowering free serum concentrations of these compounds, because they partition into the lipemic component of blood and improve the bioenergetics of the heart. Lipid emulsion has proven effective in animal models of poisoning with propranolol, a highly lipid soluble β -adrenergic antagonist, but not those that are water-soluble such as atenolol or metoprolol.^{29,31,32,34} Lipid emulsion was less effective than high-dose insulin in restoring heart rate and blood pressure in a rabbit model of propranolol poisoning.⁷¹ Human experience with the use of lipid emulsion in β -adrenergic antagonist overdose is limited, but cases of dramatic recovery from cardiac arrest have been reported.^{33,90,182,201,205} It is reasonable to administer intravenous lipid emulsion in patients with severe toxicity from a lipid-soluble β -adrenergic antagonist that does not respond to usual therapy.^{34,72} The optimal dose and formulation of lipid emulsion for this purpose is unknown. One protocol calls for a 1.5 mL/kg of 20% Intralipid followed by an infusion of 0.25 mL/kg/min. The bolus can be repeated in 3 to 5 minutes if necessary. The total dose should be less than 8 mL/kg²²¹ (Antidotes in Depth: A20).

Phosphodiesterase Inhibitors

The phosphodiesterase inhibitors amrinone, milrinone, and enoximone are theoretically beneficial in β -adrenergic antagonist overdose since they inhibit the breakdown of cAMP by phosphodiesterase and hence increase cAMP independently of β -adrenergic receptor stimulation. Phosphodiesterase inhibitors increase inotropy in the presence of β -adrenergic antagonism in both animal models¹¹⁸ and in humans.²¹³ Although these agents appear to be as effective as glucagon in animal models of β -adrenergic antagonist toxicity,^{132,185} controlled dog models were unable to demonstrate an additional benefit of these agents over glucagon.^{131,186} Phosphodiesterase inhibitors might be useful in selected patients who fail glucagon therapy, and have been used clinically to treat β -adrenergic antagonist poisoned patients.^{79,103,183,184} Therapy with phosphodiesterase inhibitors is often limited by hypotension secondary to peripheral vasodilation. Furthermore, these drugs are difficult to titrate because of relatively long half-lives (30–60 minutes for milrinone, 2–4 hours for amrinone, and ~ 2 hours for enoximone).^{94,154} For these reasons the phosphodiesterase inhibitors should generally only be considered for patients who have arterial and pulmonary artery pressure monitoring.

Ventricular Pacing

Ventricular pacing is not a particularly useful intervention in patients with β -adrenergic antagonist toxicity, but it will increase the heart rate in some patients.⁹⁵ Unfortunately, there will frequently be failure to capture or pacing may increase the heart rate with no increase in cardiac output or blood pressure.^{4,109,113,206} In fact, some authors have noticed that ventricular pacing occasionally decreases blood pressure perhaps secondary to loss of organized atrial contraction or due to impaired ventricular relaxation.²⁰⁶

Extracorporeal Removal

Extracorporeal removal is ineffective for the lipid-soluble β -adrenergic antagonists due to their large volumes of distribution. Hemodialysis may remove water-soluble renally eliminated β -adrenergic antagonists such as atenolol¹⁷⁹ and acebutolol.¹⁷⁴ Because hemodialysis is often technically difficult in poisoned patients due to hypotension and bradycardia, it is rarely utilized in patients with β -adrenergic antagonist overdose but may be considered in selected cases.

Mechanical Life Support

It is important to remember that the patient with circulatory failure from an acute overdose will typically recover without sequelae if ventilation and circulation are maintained until the xenobiotic is eliminated. When the preceding medical treatment fails, it is appropriate to consider the use of an intra-aortic balloon pump or extracorporeal life support (ECLS). Several case reports describe remarkable recoveries following the use of these therapies for refractory β -adrenergic antagonist toxicity^{21,113,146} or combined β -adrenergic antagonist and calcium channel blocker overdose.^{53,88,102,162,178,225} In one report, a neonate who developed refractory circulatory collapse from an iatrogenic overdose of propranolol was supported with extracorporeal membrane oxygenation (ECMO) for 5 days and survived neurologically intact.⁴¹ A case series documents experience with ECMO for patients with cardiac arrest caused by cardiovascular drug poisoning. In this series of six patients, two deaths were attributed to delayed institution of ECMO. The other four patients survived without sequelae.¹¹ In another series, ECLS was used in 17 patients with circulatory failure following a drug overdose. Eight patients had taken β -adrenergic antagonists either alone or in combination with other cardiovascular toxins. Thirteen of the 17 patients had long-term survival. The authors conclude that ECLS is efficient and relatively safe as a last resort treatment for patients with cardiac arrest or refractory shock following a drug overdose.³⁹ More recently, researchers compared survival with ECLS versus conventional therapy in poisoned patients with circulatory failure. Six patients in the ECLS group and ten in the conventional therapy group had ingested β -adrenergic antagonists. In this series, 12 out of 14 (86%) of the ECLS patients survived compared with 23 out of 48 (48%) in the conventional therapy group. The authors concluded that ECLS is helpful in critically ill poisoned patients who do not respond to conventional therapy.¹⁴⁴

Experimental Treatment

Vasopressin is a hypothalamic hormone that acts at G protein-coupled receptors to mediate vasoconstriction (at V_1 receptors), water retention (at V_2 receptors), and corticotropin secretion (at V_3 receptors), and may also increase the response to catecholamines. Vasopressin analogues have been used as vasopressors clinically in shock states and for patients in cardiopulmonary arrest.^{14,214} Vasopressin was as effective as glucagon but less effective than high-dose insulin in a porcine model of propranolol toxicity.^{82,83} There are no reports of vasopressin use for human β -adrenergic antagonist toxicity.

The calcium sensitizers, levosimendan and pimobendan, interact with the contractile proteins to improve cardiac function and are used clinically to treat heart failure.^{7,119,120,159} Levosimendan is both a positive inotrope and a vasodilator and has a better safety profile than pimobendan. It is approved in Europe for use in heart failure patients and is as effective as dobutamine in increasing contractility. Levosimendan infusions allow up titration of β -adrenergic antagonists in patients with severe heart failure.²²⁹ Levosimendan improved survival in a porcine model of propranolol toxicity¹²¹ and improved cardiac output in a murine model of metoprolol toxicity⁹³ but was not beneficial in a murine model of propranolol toxicity.⁹² Calcium sensitizers are not available in the United States or Canada. They may prove to have a role in managing patients poisoned with β -adrenergic antagonists.

Fructose 1,6-diphosphate (FDP) is an intermediate in the glycolytic pathway. FDP is able to cross cell membranes and it increases cardiac contractility.^{155,208} Compared with glucose infusion, FDP infusion resulted in improved survival in murine models of propranolol toxicity and verapamil toxicity.⁹¹ FDP may prove to have a role in the management of β -adrenergic antagonist poisoning, but it cannot be recommended at this time.

Special Circumstances

The preceding discussion applies to the generic management of β -adrenergic antagonists. Certain β -adrenergic antagonists have unique properties that modify their toxicity. The management considerations for these unique agents are discussed as follows.

Sotalol

In addition to bradycardia and hypotension, sotalol toxicity may result in a prolonged QT interval and ventricular dysrhythmias including torsade de pointes. Sotalol induced bradycardia and hypotension should be managed as with other β -adrenergic antagonists. Specific management of patients with sotalol overdose includes correction of hypokalemia and

hypomagnesemia. Overdrive pacing and magnesium infusions may be effective for sotalol-induced torsade de pointes.^{8,211} Lidocaine is also effective for sotalol-induced torsade de pointes.¹⁰ In the future, potassium channel openers such as the cardioprotective drug nicorandil may prove effective for sotalol-induced torsade de pointes.^{192,207,218}

Peripheral Vasodilation (Betaxolol, Bucindolol, Carteolol, Carvedilol, Celiprolol, Labetalol, Nebivolol)

Treatment of patients who have overdosed with one of the vasodilating β -adrenergic antagonists is similar to that for patients who ingest other β -adrenergic antagonists. Decisions about the need for vasopressors should be guided by clinical findings. If vasodilation is a prominent feature, high doses of vasopressors with α -adrenergic agonist properties (eg, norepinephrine or phenylephrine) may be required.⁷⁸ Conversely, if β -adrenergic antagonism is prominent, xenobiotics that act to increase intracellular cAMP, like glucagon, may be needed.^{74,103}

Membrane Stabilizing Effects (Acebutolol, Betaxolol, Carvedilol, Oxprenolol, Propranolol)

It might be expected that hypertonic sodium bicarbonate would be beneficial in treating the ventricular dysrhythmias that occur with these β -adrenergic antagonist. Unfortunately there is limited experience with the use of sodium bicarbonate in this situation, and the experimental data are mixed. Sodium bicarbonate was not beneficial in a canine model of propranolol toxicity, although there was a trend toward QRS interval narrowing in the sodium bicarbonate group.¹³⁰ In models with propranolol poisoned isolated rat hearts, however, hypertonic sodium chloride proved beneficial.^{97,98} Perhaps most compelling is the fact that sodium bicarbonate appeared to reverse ventricular tachycardia in a human case of acebutolol poisoning.⁴⁴ Because sodium bicarbonate is a relatively safe and simple intervention, we would recommend that it be used in addition to standard therapy for β -adrenergic antagonist poisoned patients with QRS widening, ventricular dysrhythmias, or severe hypotension. Sodium bicarbonate would not be expected to be beneficial in sotalol induced ventricular dysrhythmias and, by causing hypokalemia, may actually increase the risk of torsade de pointes. The usual dose of hypertonic sodium bicarbonate is 1 to 2 mEq/kg given as an intravenous bolus. This may be followed by an infusion or repeated boluses may be given as needed. Care should be taken to avoid severe alkalosis or hypokalemia (Antidotes in Depth: A5).

Observation

All patients who have bradycardia, hypotension, abnormal ECG findings, or CNS toxicity following a β -adrenergic antagonist overdose should be observed in an intensive care setting until these findings resolve. Toxicity from regular release β -adrenergic antagonist poisoning other than with sotalol almost always occurs within the first 6 hours.^{126,129,167} Therefore patients without any findings of toxicity following an overdose of a regular release β -adrenergic antagonist other than sotalol may be discharged from medical care after an observation time of 6 to 8 hours if they remain asymptomatic with normal vital signs and normal ECG and have had gastrointestinal decontamination with activated charcoal. Ingestion of extended-release preparations may be associated with delayed toxicity, and these patients should be observed for 24 hours in an intensive care unit. Patients who may have delayed absorption because of a mixed overdose or underlying gastrointestinal disease may also require longer observation. Sotalol toxicity may also be delayed with ventricular dysrhythmias first occurring as late as 9 hours after ingestion.¹⁵⁶ We recommend that all patients with sotalol overdose be monitored for at least 12 hours. Patients who remain stable without QT prolongation may then be discharged from a monitored setting.

SUMMARY

- β -Adrenergic antagonists are commonly used to treat hypertension, angina, tachydysrhythmias, tremor, migraine, and panic attacks.
- Overdoses of β -adrenergic antagonists are relatively uncommon but continue to cause deaths worldwide.
- Patients who develop symptoms after ingesting regular release β -adrenergic antagonists do so within the first 6 hours. Sotalol ingestions are an exception to this and may cause delayed and prolonged toxicity. Extended release formulations may also result in delayed toxicity and require 24 hour observation.
- Patients with consequential β -adrenergic antagonist overdose typically develop bradycardia and hypotension.
- Propranolol and other β -adrenergic antagonists with membrane-stabilizing properties and high lipid solubility are the most toxic in overdose. These xenobiotics cause prolongation of the QRS interval, severe hypotension, coma, seizures, and apnea.
- Sotalol is unique in its ability to prolong the QT interval and its toxicity often results in refractory ventricular

dysrhythmias, which may respond to overdrive pacing or to magnesium infusions.

- In addition to supportive care, the most important therapy for β -adrenergic antagonist toxicity is glucagon. High doses of insulin together with glucose provide a promising new treatment modality. Catecholamine infusions may also be helpful but should be closely monitored and large doses are typically required. Patients who fail treatment with glucagon, insulin, and catecholamines are critically ill and may respond to intravenous fat emulsion therapy, phosphodiesterase inhibitors, or mechanical support of circulation. Fortunately, most patients respond to simpler measures and this aggressive therapy is rarely required.

A18 ANTIDOTES IN DEPTH

Glucagon

Mary Ann Howland

INTRODUCTION

The traditional role of glucagon was to reverse life-threatening hypoglycemia in patients with diabetes unable to receive dextrose in the outpatient setting. However, in medical toxicology, glucagon is used “off label” early in the management of β -adrenergic antagonist and calcium channel blocker toxicity to increase heart rate, contractility, and blood pressure by increasing myocardial cyclic adenosine monophosphate (cAMP) via a non- β -adrenergic receptor mechanism of action. The use of glucagon is based primarily on animal studies and as well as human case series and case reports. The effects of glucagon are often transient.

HISTORY

Glucagon was discovered in 1923, just 2 years after the discovery of insulin.¹⁰ The positive inotropic and chronotropic effects have been known since the 1960s.^{12,15}

PHARMACOLOGY

Chemistry/Preparation

Glucagon is a polypeptide counterregulatory hormone with a molecular weight of 3500 Da, secreted by the α cells of the pancreas. Previously animal derived, and possibly contaminated with insulin, the form approved by the US Food and Drug Administration (FDA) has been synthesized by recombinant DNA technology since 1998; therefore, it no longer contains any insulin.²⁵

Mechanism of Action

In both animals and humans, glucagon receptors can be found in the heart, brain, and pancreas.^{22,33,64} Binding of glucagon to cardiac receptors is closely correlated with activation of cardiac adenylate cyclase (AC).⁵² A large number of glucagon binding sites are demonstrated, and as little as 10% occupancy produces near maximal stimulation of adenylate cyclase. Binding of glucagon to its receptor results in coupling with two isoforms of the G_s protein and catalyzes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate on the α subunit of the G_s protein.^{21,51,69} One isoform is coupled to β agonists, while both isoforms are coupled to glucagon.⁶⁹ The GTP- G_s units stimulate adenylate cyclase to convert adenosine triphosphate (ATP) to cAMP.^{32,40} In animal hearts, glucagon inhibits the phosphodiesterase PDE-3.^{5,43} Selective inhibition of PDE-4 potentiated the cAMP response to glucagon in adult rat ventricular myocytes.⁵⁰ Glucagon, along with β_2 agonists, histamine, and serotonin (but not β_1 agonists), also activates G_i , which inhibits cAMP formation in human atrial heart tissue.²⁷

Evidence now suggests an additional mechanism of action for glucagon, independent of cAMP, and dependent on arachidonic acid.⁵⁷ Cardiac tissue metabolizes glucagon, liberating mini-glucagon, an apparently active smaller terminal fragment.^{57,66} Mini-glucagon stimulates phospholipase A_2 , releasing arachidonic acid. Arachidonic acid acts to increase cardiac contractility through an effect on calcium. The effect of arachidonic acid—and therefore of mini-glucagon—is synergistic with the effect of glucagon and cAMP.⁵⁸

Stimulation of glucagon receptors in the liver and adipose tissue increases cAMP synthesis, resulting in glycogenolysis, gluconeogenesis, and ketogenesis.³² Other properties of glucagon include relaxation of smooth muscle in the lower esophageal sphincter, stomach, small and large intestines, common bile duct, and ureters.^{18,21,30}

Cardiovascular Effects

Investigations of the mechanism of action of glucagon on the heart have been performed on cardiac tissue obtained from patients during surgical procedures and in a variety of in vivo and ex vivo animal studies. The results are often species specific and are affected by the presence or absence of congestive heart failure. The inotropic action of glucagon is likely related to an increase in cardiac cAMP concentrations.^{12,32,40} Both the positive inotropic^{3,15,38,45} and chronotropic^{3,12,15,30,38,40,45,67} actions of glucagon are very similar to those of the β -adrenergic agonists, except that they are not blocked by β -adrenergic antagonists.⁶⁹ Although in some canine experiments glucagon caused ventricular tachycardia, glucagon is not dysrhythmogenic in patients with severe chronic congestive heart failure, myocardial infarction-related acute congestive heart failure, or in postoperative patients with myocardial depression.^{26,34,39,42} The effects of glucagon diminish markedly as the severity and chronicity of congestive heart failure increases.⁴⁵

Volunteer Studies

Cardiovascular effects were extensively studied in 21 patients with heart failure who were given varied doses and durations of glucagon therapy.⁴⁶ Eleven patients who received 3 to 5 mg via intravenous (IV) bolus had increases in the force of contraction, as measured by maximum dP/dT (upstroke pattern on apex cardiogram), heart rate, cardiac index, blood pressure, and stroke work. There was no change in systemic vascular resistance, left ventricular end-diastolic pressure, or stroke index. Additionally, glucose concentrations increased by 50% and the potassium concentrations fell. A study of nine patients demonstrated a 30% increase in coronary blood flow following a 50 μ g/kg IV dose.⁴² Patients who received 1 mg via IV bolus also had an increase in cardiac index, but systemic vascular resistance fell, probably secondary to splanchnic and hepatic vascular smooth muscle relaxation.⁴⁶ Patients who received an infusion of 2 to 3 mg/min for 10 to 15 minutes responded similarly to those who received the 3 to 5 mg IV boluses, but patients receiving boluses experienced significant dose limiting nausea and vomiting.⁴⁶

Pharmacokinetics and Pharmacodynamics

The volume of distribution of glucagon is 0.25 L/kg.¹⁶ The plasma, liver, and kidney extensively metabolize glucagon with an elimination half-life of 8 to 18 minutes.¹⁶ In human volunteers following a single IV bolus, the cardiac effects of glucagon begin within 1 to 3 minutes, are maximal within 5 to 7 minutes, and persist for 10 to 15 minutes.⁴⁵ The time to maximal glucose concentration is 5 to 20 minutes, with a duration of action of 60 to 90 minutes.¹⁶ Smooth muscle relaxation begins within 1 minute and lasts 10 to 20 minutes.¹⁶ The onset of action following intramuscular and subcutaneous administration occurs in about 10 minutes, with a peak at about 30 minutes.¹⁶

Activation of AC in adipose, myocardial, and hepatic tissue and myocardial contractility requires pharmacologic levels of glucagon, exceeding 0.1 nM.⁵² At physiologic concentrations of glucagon below 0.1 nM, it appears to duplicate the cardiac metabolic effects of insulin by activating a phosphatidylinositol-3 kinase (PI3K)-dependent signal without stimulating AC.⁵² Tachyphylaxis or desensitization of receptors may occur with repetitive dosing. Experimental heart preparations exposed to glucagon for varying lengths of time demonstrated a decrease in the amount of generated cAMP.^{24,70} Possible explanations for tachyphylaxis include uncoupling from the glucagon receptor, increased PDE hydrolysis of cAMP, or both.^{24,66,70,73} Other experiments demonstrated a transient effect of glucagon on contractility and hyperglycemia, also suggesting tachyphylaxis.^{20,26}

ROLE IN THE MANAGEMENT OF OVERDOSES WITH β -ADRENERGIC ANTAGONISTS

Overdoses with β -adrenergic antagonists are particularly dangerous and are manifested by hypotension, bradycardia, prolonged atrioventricular conduction times, depressed cardiac output, and cardiac failure. Other noncardiovascular effects include alterations in consciousness, seizures, and, rarely, hypoglycemia.^{1,14,19,65} Management is often complicated, and many therapies, including atropine, isoproterenol, epinephrine, norepinephrine, dopamine, dobutamine, and various combinations, are used with variable success.^{13,14} Recently high dose insulin with dextrose (Antidotes in Depth: A17), and in the event of a cardiac arrest, IV fat emulsion (Antidotes in Depth: A20), have been added to the armamentarium. Animal studies document the ability of glucagon to increase contractility, restore the sinus node function after sinus node arrest, increase atrioventricular conduction, and rarely improve survival.^{2,36,45,55} In canine studies, high-dose insulin euglycemia (HIE) therapy has a more sustained effect on hemodynamic parameters and an improved survival rate compared with glucagon.²⁶ Glucagon has successfully reversed bradydysrhythmias and hypotension in patients unresponsive to the aforementioned traditional xenobiotics, and should be administered early in the management of patients with severe overdoses.^{54,63} By increasing myocardial cAMP concentrations independent of the β receptor,^{36,44} glucagon is able to

increase inotropy^{3,15,38,45} and chronotropy.^{3,15,38,45,67}

Glucagon successfully reversed the bradycardia, low-output heart failure, and hypotension that developed in a premature newborn, presumably as a result of an inappropriately large prenatal dose of labetalol given to the mother. This neonate, delivered at 32 weeks' gestation and weighing 1.8 kg, received 0.3 mg/kg glucagon IV initially and five additional doses of 0.3 to 0.6 mg/kg over the next 5 hours, with improvement in heart rate, blood pressure, and perfusion. Epinephrine and diuretics were also used.⁵⁹

Combined Effects with Phosphodiesterase Inhibitors and Calcium

Strategies for enhancing the effects of glucagon have involved combining it with the PDE-3 inhibitor amrinone (inamrinone), its derivative milrinone, and most recently rolipram, a selective PDE-4 inhibitor. In a canine model of propranolol toxicity, both amrinone (inamrinone) and milrinone, alone were comparable with glucagon,^{36,56} but the combination of amrinone and glucagon resulted in a decrease in mean arterial pressure.³⁵ Tachycardia occurred when milrinone was used with glucagon.⁵⁵ In an ex vivo model using strips of rat ventricular heart, rolipram enhanced the inotropic effect of glucagon and limited glucagon tachyphylaxis.²⁴ However, because the evidence for the effectiveness of HIE was demonstrated in animal models and human case reports, combining glucagon with a phosphodiesterase inhibitor is no longer recommended.

The relationship between calcium and the chronotropic effects of glucagon was demonstrated in rats.⁸ Maximal chronotropic effects of glucagon are dependent on a normal circulating ionized calcium. Both hypocalcemia and hypercalcemia blunt the maximal chronotropic response.^{7,8}

ROLE IN CALCIUM CHANNEL BLOCKER OVERDOSE

Calcium channel blocker overdoses produce a constellation of clinical findings similar to those recognized with β -adrenergic antagonist overdoses, including hypotension, bradycardia, conduction block, and myocardial depression. Animal studies^{2,23,53,60,61,71,72} demonstrate the ability of glucagon to improve heart rate, atrioventricular conduction, and reverse the myocardial depression produced by nifedipine, diltiazem, and verapamil. However, there was no survival benefit attributed to glucagon in these studies, while a canine model of verapamil overdose comparing glucagon to HIE only revealed a survival benefit for HIE.^{2,28} Human case reports demonstrate improved hemodynamics.^{11,41,44,62}

ROLE IN REVERSAL OF HYPOGLYCEMIA

Glucagon was once proposed as part of the initial treatment for all comatose patients because it stimulates glycogenolysis in the liver.⁴⁹ The theoretical rationale for this approach is only partially sound in that glucagon requires time to act and may be ineffective in a patient with already depleted glycogen stores. Patients with type 2 diabetes are more likely to respond than are patients with type 1 diabetes. The IV administration of 0.5 to 1.0 g/kg of 50% dextrose in adults rapidly reverses hypoglycemia and does not rely on glycogen stores for its effect. Therefore, IV dextrose is preferred over glucagon as the initial substrate to be given to all patients with an altered mental status presumed to be related to hypoglycemia (Antidotes in Depth: A12). Glucagon may retain some role as a temporizing measure, until medical help can be obtained, in settings such as in the home where IV dextrose is not an option, or when IV access is not rapidly available.

In patients with insulinoma, after an initial hyperglycemic response glucagon may actually worsen hypoglycemia, as the result of a feedback increase in insulin.

ADVERSE EFFECTS AND SAFETY ISSUES

Side effects associated with glucagon include dose-dependent nausea, vomiting,³⁹ hyperglycemia, hypoglycemia, and hypokalemia; relaxation of the smooth muscle of the stomach, duodenum, small bowel, and colon; and, rarely, urticaria, respiratory distress, and hypotension.^{16,39} Hypotension is reported up to 2 hours after administration in patients receiving glucagon as premedication for upper gastrointestinal endoscopy procedures.¹⁶ The hyperglycemia is followed by an immediate rise in insulin, which causes an intracellular shift in potassium, resulting in hypokalemia.^{20,39,45} It is unclear whether stimulation of the Na^+ - K^+ -ATPase in skeletal muscle also contributes to the hypokalemia as occurs with β -adrenergic agonists.^{29,48} Glucagon may increase the anticoagulant effect of warfarin.¹⁶

Glucagon can also increase the release of catecholamines in a patient with a pheochromocytoma, resulting in a hypertensive crisis,²⁰ which can be treated with phentolamine.¹⁶ Continuous prolonged treatment with glucagon might lead to a dilated cardiomyopathy, as was reported in a patient with a glucagonoma.⁶

PREGNANCY AND LACTATION

Glucagon is FDA pregnancy category B. It is presumed that benefit exceeds risk. There are no reports of glucagon use during lactation. However, the size and peptide nature of glucagon suggest that the exposure to a lactating infant would be limited.

DOSAGE AND ADMINISTRATION

An initial IV bolus of 50 µg/kg, infused over 1 to 2 minutes, is recommended (3–5 mg in a 70-kg person).¹⁴ If clinically acceptable, then a longer duration of infusion may be used to minimize vomiting. Higher doses may be necessary if the initial bolus is ineffective, and up to 10 mg can be used in an adult.²² Using too small a dose can potentially decrease systemic vascular resistance.⁴⁶ In some cases, the bolus dose should be followed by a continuous infusion of 2 to 5 mg/h (≤ 10 mg/h) in 5% dextrose in water, which can be tapered as the patient improves.^{1,21,22,47,54,65} This dosing regimen has never been studied and is based on case reports. Experimental heart preparations clearly demonstrate tachyphylaxis with continuous administration. Whether this occurs in humans is unclear, but might argue for repeated bolus infusions over 1 to 5 minutes rather than continuous infusion.^{24,70} In addition, the smooth muscle relaxation associated with a continuous infusion would be assumed to impede attempts at gastrointestinal decontamination with multiple-dose activated charcoal or whole-bowel irrigation.

FORMULATION AND ACQUISITION

Glucagon [rDNA origin] for injection is available as a sterile, lyophilized white powder in a vial, alone, or accompanied by Sterile Water for Reconstitution, also in a vial. It is also supplied in the form of a kit for treatment of hypoglycemia with one vial containing 1 mg (1 unit) of glucagon [rDNA origin] for injection with a disposable prefilled syringe containing Sterile Water for Reconstitution, as well as a “10-pack” with 10 vials, each containing 1 mg (1 unit) GlucaGen (glucagon [rDNA origin] for injection). The glucagon powder should be reconstituted with 1 mL of sterile water for injection, after which the vial should be shaken gently until the powder completely dissolves. The final solution should be clear, without visible particles.¹⁶ The reconstituted glucagon should be used immediately after reconstitution, and any unused part discarded. Concentrations greater than 1 mg/mL should not be used. An adequate supply of glucagon in the emergency department is at least 20 1-mg vials, with assurance of another 30 mg in the pharmacy.^{9,37}

SUMMARY

- Glucagon can produce positive inotropic and chronotropic effects despite β-adrenergic antagonism and calcium channel blockade.
- Glucagon is often beneficial in the treatment of patients with severe overdoses of β-adrenergic antagonists and calcium channel blockers.
- The effects of glucagon may not persist and other therapies, such as insulin and dextrose, should also be considered (Chaps. 61 and 62).
- The relatively benign character of an IV bolus of glucagon in the patient with a serious overdose of a β-adrenergic antagonist or calcium channel blocker should lead the clinician to use glucagon early in patient management.
- Nausea and vomiting should be anticipated and managed.

63 MISCELLANEOUS ANTIHYPERTENSIVES AND PHARMACOLOGICALLY RELATED AGENTS

Francis Jerome DeRoos

Hypertension is one of the commonest chronic medical problems and one of the most readily amenable to pharmacotherapy. Beginning in the 1960s, when asymptomatic hypertension was linked to significant adverse effects such as stroke, myocardial infarction, and sudden death, antihypertensive pharmacotherapeutics began being used. The first generation included centrally acting, sympatholytics, direct vasodilators, sodium nitroprusside, and diuretics. Unfortunately, these often had significant adverse events, leading to the development of β -adrenergic antagonists, calcium channel blockers (CCBs), angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and, more recently, direct renin inhibitors (DRIs). This chapter reviews the first-generation antihypertensives, as well ACEIs, ARBs, and DRIs. In general, the majority of antihypertensives manifest clinical signs and symptoms in terms of the degree of hypotension produced. Particular attention will be placed on mechanisms of action and unique toxicologic considerations for each of these xenobiotics.

CLONIDINE AND OTHER CENTRALLY ACTING ANTIHYPERTENSIVES

Clonidine is an imidazoline compound that was synthesized in the early 1960s. Because of its potent peripheral α_2 -adrenergic agonist effects, it was initially studied as a potential topical nasal decongestant. However, hypotension was a common adverse event, which redirected its consideration for other therapeutic applications.¹⁰⁵ Clonidine is the best understood and the most commonly used of all the centrally acting antihypertensives, a group that includes methyldopa, guanfacine, and guanabenz. Although these drugs differ chemically and structurally, they all decrease blood pressure in a similar manner. The imidazoline compounds oxymetazoline and tetrahydrozoline, which are used as ophthalmic topical vasoconstrictors and nasal decongestants, produce similar systemic effects when ingested.¹⁰⁵

Since 1985, the increased efficacy and improved adverse event profiles of the newer antihypertensives have diminished the use of the α_2 -adrenergic agonists in routine hypertension management. However, their use is increasing as a result of a wide variety of applications, including attention-deficit/hyperactivity disorder (ADHD), peripheral nerve and spinal anesthesia, and as an adjunct in the management of opioid, ethanol, and nicotine withdrawal.^{120,127,130,224} In addition, abuse of clonidine may be a growing problem in opioid dependent patients, and it has been used in criminal acts of chemical submission.^{20,145}

Although centrally acting α_2 -adrenergic agonist exposure is relatively uncommon, it may cause significant toxicity, particularly in children. One report from two large pediatric hospitals identified 47 children requiring hospitalization for unintentional clonidine ingestions over a 5-year period.²⁶⁶ Significant clonidine poisoning has also resulted from formulation and dosing errors in children.^{211,241} Imidazolines used as ocular vasoconstrictors have resulted in significant systemic toxicity, especially when ingested.^{109,150,137,202}

Pharmacology

Clonidine and the other centrally acting antihypertensives exert their hypotensive effects primarily via stimulation of presynaptic α_2 -adrenergic receptors in the brain.^{78,194,218,257} This central α_2 -adrenergic receptor agonism enhances the activity of inhibitory neurons in the vasoregulatory regions of the central nervous system (CNS), notably the nucleus tractus solitarius in the medulla, resulting in decreased norepinephrine release.²¹⁷ This results in decreased sympathetic outflow from the intermediolateral cell columns of the thoracolumbar spinal tracts into the periphery^{2,256} and reduces the heart rate, vascular tone, and, ultimately, arterial blood pressure.^{186,256} This centrally mediated sympatholytic effect is modulated by nitric oxide and γ -aminobutyric acid (GABA), which may explain some of the clinical variability that occurs among patients who have overdosed with clonidine.^{37,87,234,260}

Pharmacokinetics

Clonidine is well absorbed from the gastrointestinal (GI) tract (~ 75%) with an onset of action within 30 to 60 minutes. The peak serum concentration occurs at 2 to 3 hours and lasts as long as 8 hours.⁵⁹ Clonidine has 20% to 40% protein binding and an apparent volume of distribution of 3.2 to 5.6 L/kg.¹³⁸ The majority of clonidine is eliminated unchanged via the kidneys.¹⁴³

Clonidine is available in both oral and patch form. The patch, referred to as the clonidine transdermal therapeutic system, allows slow, continuous delivery of drug over a prolonged period of time, typically one week. This formulation, however, offers unique clinical challenges. Each patch contains significantly more drug than is typically delivered during the prescribed duration of use. For example, while a patch that delivers 0.1 mg/day of clonidine contains a total of 2.5 mg, the product that delivers 0.3 mg/day and contains a total of 7.5 mg.³⁶ Even after one week of use, between 35% and 50% and, in some instances, as much as 70%, of the drug remains in the patch.^{36,98} Puncturing the outer membrane layer or backing opens the drug reservoir and allows a significant amount of the drug to be released rapidly. In addition, patients do not perceive this delivery system as a medication, and they may not exercise appropriate precautions. For example, discarding a used patch in an open wastebasket provides toddlers, who often are fascinated with stickers and other adhesive objects, an opportunity to remove the patch and apply, taste, or ingest it. Numerous reports of toxicity in both adults and children have resulted from dermal exposure, mouthing, or ingesting one clonidine patch, emphasizing this concern.^{36,47,98,102,124,204,205}

Guanabenz and guanfacine are structurally and pharmacologically very similar to each other. They are well absorbed orally, achieving peak concentrations within 3 to 5 hours, and both have large volumes of distribution (4–6 L/kg for guanfacine, 7–17 L/kg for guanabenz).^{109,237} Whereas guanabenz is metabolized predominantly in the liver and undergoes extensive first-pass effect, guanfacine is eliminated equally by the liver and kidney.^{109,237} The metabolism of neither drug results in the production of significant active metabolites.

Whereas clonidine, guanabenz, and guanfacine are all active drugs with direct α_2 -adrenergic agonist effects, methyl dopa is a prodrug. It enters the CNS, probably by an active transport mechanism, before it is converted into its pharmacologically active degradation products.²² α -Methylnorepinephrine is the most significant of its metabolites, although α -methyl dopamine and α -methylepinephrine may also be important.^{75,101,210} These metabolites are direct α_2 -adrenergic agonists and impart their hypotensive effect as do the other centrally acting antihypertensives. Approximately 50% of an oral dose of methyl dopa is absorbed, and peak serum concentrations are achieved in 2 to 3 hours.¹⁷⁰ However, because methyl dopa requires metabolism into its active form, these concentrations have little correlation with its clinical effects. Methyl dopa has a small volume of distribution (0.24 L/kg) and little protein binding (15%).¹⁷⁰ It is eliminated in the urine, both as parent compound and after hepatic sulfation.¹⁷⁹

Pathophysiology

In therapeutic oral dosing, clonidine and the other centrally acting antihypertensives have little effect on the peripheral α_2 receptors, the peripheral sympathetic nervous system, or the normal circulatory responses that occur with exercise or the Valsalva maneuver.^{169,183} However, when serum concentrations increase above 2 ng/mL, as in the setting of intravenous (IV) administration or oral overdose, peripheral postsynaptic α_2 -adrenergic stimulation may occur, causing increased norepinephrine release and producing vasoconstriction and hypertension.^{44,53,173,243} This hypertension is short lived, however, because the potent centrally mediated sympathetic inhibition becomes the predominant effect, and hypotension ensues.^{4,154,168,210} Imidazoline specific binding sites are identified both in the rostral ventrolateral medulla and in coronary artery vascular smooth muscle and may be important in the clinical effects of these xenobiotics although their exact function has not been elucidated.^{210,248} Direct stimulation of these imidazoline binding sites appears to lower blood pressure independent of central α_2 -adrenergic effects.^{24,62} Therefore, although their precise physiologic relationship has not been clearly elucidated, more evidence supports the concept that both imidazoline and α_2 -adrenergic receptors modulate the ability of clonidine, and presumably other centrally acting antihypertensives, to inhibit central norepinephrine release and the cardiovascular effects.^{25,62,99,163}

Clinical Manifestations

Although the majority of the published cases involve clonidine, the signs and symptoms of poisoning with any centrally acting antihypertensive are similar. The CNS and cardiovascular toxicity reflect an exaggeration of their pharmacologic action. Common signs include CNS depression, bradycardia, hypotension, and (occasionally) hypothermia.^{6,192,227,253} Most patients who ingest clonidine or the other similarly acting drugs manifest symptoms rapidly, typically within 30 to 90 minutes.²⁶⁶ The exception may be methyl dopa, a prodrug, which requires metabolism to be activated, possibly delaying toxicity for hours.^{227,270}

CNS depression is the most frequent clinical finding and may vary from mild lethargy to coma.^{149,154,182,203} In addition,

severely obtunded patients may experience decreased ventilatory effort and hypoxia.⁴ Respirations may be slow and shallow, with intermittent deep, sighing breaths. Various other terms are used to describe this phenomenon, including gasping, Cheyne-Stokes respirations, and periodic apnea.^{6,10,124,154} This hypoventilation is characteristically responsive to tactile stimuli in children, although mechanical ventilation may be required in severe cases.^{4,6,103,124} The associated CNS depression typically resolves over 12 to 36 hours.^{10,182} Other manifestations of this CNS depression include hypotonia, hyporeflexia, and irritability.^{44,154,239} The cranial nerve examination often demonstrates miotic pupils that may remain reactive to light.^{4,6,245} Two unusual case reports describe seizures in the setting of clonidine poisoning,^{44,146} the mechanism of which is unclear.

Hypothermia is associated with overdoses involving centrally acting antihypertensives.^{6,154,192,210} This is thought to be a consequence of α -adrenergic effects within the thermoregulatory center, although other authors suggest that these drugs activate central serotonergic pathways that alter normal thermoregulation.^{138,161} Although this phenomenon may last several hours, it rarely requires treatment and responds well to passive rewarming.^{44,192}

Sinus bradycardia may occur in up to 50% of patients who ingest clonidine and it results from the combination of an exaggerated centrally mediated sympatholytic effect, a centrally mediated increase in vagal tone, or a direct stimulation of α_2 -adrenergic receptors on the myocardium.^{55,132,239,256,266,267}

Other conduction abnormalities, including first degree heart block, type 1 and 2 Mobitz atrioventricular block, and complete heart block, are described both in overdose and after therapeutic dosing.^{123,182,218,220,254,267} It appears that very young patients and patients who have underlying sinus node dysfunction, concurrent sympatholytic drug therapy, or chronic kidney disease (CKD) are at particular risk of developing bradydysrhythmia after central antihypertensive ingestion.^{31,239,247}

Hypotension is the major cardiovascular manifestation of central antihypertensive toxicity.^{6,36,182,222,239,266} While studies have suggested a doseresponse relationship between the history of the quantity of the centrally acting antihypertensive ingested and the severity of the clinical manifestations, clonidine ingestions as small as 0.2 mg have resulted in clinically severe poisoning, mandating the necessity to individually assess each exposure; the presence of any symptoms should prompt immediate medical evaluation.^{18,182} Fatalities from any of these xenobiotics are rare, with few published reports from the American Association of Poison Control Centers (AAPCC) database²⁹ (Chap. 136).

After deaths of four children who were prescribed clonidine were reported, concerns that there was a causal association between combination clonidine–methylphenidate therapy and sudden death were raised.^{35,71} Fortunately, closer scrutiny of these cases revealed significant confounders, and a formal investigation by the US Food and Drug Administration (FDA) concluded that there was inadequate evidence to confirm this association.^{71,199,242,266}

Withdrawal

Abrupt cessation of central antihypertensive therapy may result in withdrawal that is characterized by excessive sympathetic activity. Symptoms include agitation, insomnia, tremor, palpitations, tachycardia, and hypertension, that begin between 16 and 48 hours after cessation of therapy.^{95,206} Ventricular tachycardia and myocardial infarction may occur in patients with clonidine withdrawal.^{19,172,193} The frequency and severity of symptoms appear to be greater in patients treated with higher doses for several months and in those with the most severe pretreatment hypertension.²⁰⁶ Shorter-acting drugs such as clonidine and guanabenz are more frequently associated with withdrawal.^{30,82,201,269} Due to the prolonged and continuous exposures, children being treated with extended release guanfacine formulations and transdermal patches, may be placed at greater risk of developing withdrawal upon cessation. The mechanism for this hyperadrenergic phenomenon appears to involve an increase in CNS noradrenergic activity in the setting of decreased α_2 -receptor sensitivity.⁶⁵ Reasonable treatment strategies include administering clonidine or benzodiazepines, via either the oral or IV route, followed by a closely monitored tapering of the dosing over several weeks. Animal and human data suggest that β -adrenergic antagonists, including labetalol, are contraindicated in clonidine withdrawal.^{9,117} Esmolol exacerbates this paradoxical hypertension in a manner similar to that which occurs when these xenobiotics are used in cocaine toxicity by inducing unopposed α_1 -receptor stimulation (Chap. 78).

Diagnostic Testing

Clonidine and other centrally acting antihypertensives are not routinely included in serum or urine toxicologic assays. Consequently, management decisions should be based on clinical parameters. No electrolyte or hematologic abnormalities are associated with this exposure. Because of the potential for bradydysrhythmia and hypoventilation, 12-lead electrocardiography (ECG) and continuous cardiac and pulse oximetry monitoring are recommended.

Management

Appropriate therapy begins with particular focus on the patient's respiratory and hemodynamic status. Administration of activated charcoal (AC) is the primary mode of GI decontamination in most cases of ingestion. Patients often present after the onset of symptoms rather than immediately after ingestion, and patients respond well to supportive care. In cases involving clonidine patch ingestions, whole-bowel irrigation appears to be an effective intervention.¹⁰²

All patients with CNS depression should be evaluated for hypoxia and hypoglycemia. Those with respiratory compromise, including apnea, often respond well to simple auditory or tactile stimulation.^{4,6,103,124} Significant arousal during preparation for intubation often precludes the need for mechanical ventilation.⁴ Endotracheal intubation should be performed if clinically indicated.

Patients with isolated hypotension should initially be treated with IV boluses of crystalloid: 20 mL/kg in children and 500 to 1000 mL in adults. Bradycardia is typically mild and usually does not require any therapy if adequate peripheral perfusion exists. If the symptomatic bradycardia occurs, then atropine is often effective and redosing may be required.^{4,6,149,239}

It is likely that naloxone was first used in clonidine-poisoned patients because of their clinical findings of CNS and respiratory depression and miosis is similar to opioid-poisoned patients.¹⁷⁴ Clonidine-poisoned patients, particularly children, may have increased arousal, respiratory effort, heart rate, and blood pressure after naloxone administration.^{10,129,174,245} The mechanism for this may relate to modulation of CNS sympathetic outflow by endogenous CNS opioids.^{26,70,116,222}

This concept is supported by a clinical study in which clonidine administration to hypertensive patients for 3 days resulted in a significant decrease in blood pressure. Subsequent administration of 0.4 mg of naloxone parenterally reversed the decrease in blood pressure and heart rate in almost 60% of the patients.⁶⁹ Because of the short duration of effects of naloxone (20–60 minutes) redosing or continuous infusion may be required. As with some synthetic opioids, such as propoxyphene and fentanyl, clinical improvement may occur only after high doses (4–10 mg) of naloxone,^{124,152} and some patients have no response regardless of dose used.^{149,266}

Early onset hypertension is typically self limited and therapy should be cautiously undertaken. If hypertension is severe or prolonged, then treatment with a short acting and titratable antihypertensive such as IV nicardipine and sodium nitroprusside is appropriate.¹⁵⁴ Esmolol may exacerbate this paradoxical hypertension in a manner similar to that which occurs when these xenobiotics are used in cocaine toxicity by inducing unopposed α_1 -receptor stimulation ([Chap. 78](#)). Although oral nifedipine has been used,⁵⁸ its inability to titrate and its unpredictable efficacy make its use inappropriate as well.

CENTRAL IMIDAZOLINE AGONISTS

Moxonidine and related rilmenidine are also known as second-generation centrally acting antihypertensives and are the newest class of antihypertensives available in the United States.⁶² They are structurally similar to clonidine, but selectively attach at I_1 -imidazoline binding sites which are found predominantly in the rostral ventrolateral medulla, and they have much less affinity for the α_2 -adrenergic receptor.⁶⁶ The exact molecular structure of these imidazoline binding sites has not been determined nor has the exact physiologic cascade or effect of ligand binding at these sites. Therefore these sites are not currently termed “receptors.” Although the exact mechanism of action is still being investigated, binding at these I_1 -imidazoline specific sites ultimately leads to sympathetic outflow from the medulla, vasodilation, and reduction in blood pressure. Nitric oxide or GABA mechanisms may be involved in their central effects.^{190,191} Therapeutically, moxonidine is used both as monotherapy or in combination with the antihypertensives. Patients with diabetes or metabolic syndrome may particularly benefit from moxonidine because of its positive effects on insulin resistance, impaired glucose tolerance, and hyperlipidemia.^{62,72} There is one published overdose resulted in initial hypertension and somnolence suggesting that weak α_2 -adrenergic receptor affinity is overwhelmed in overdose.¹⁴⁸ This patient subsequently had two seizures that were responsive to benzodiazepines however never developed any hypotension.¹⁴⁸

OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Several other xenobiotics also exert their antihypertensive effect by decreasing the effects of the sympathetic nervous system. Often termed sympatholytics, they can be classified as ganglionic blockers, presynaptic adrenergic blockers, or α_1 -adrenergic antagonists, depending on their mechanism of action. These drugs are rarely used clinically, and little is known about their effects in overdose.

Presynaptic Adrenergic Antagonists

Guanethidine

These xenobiotics exert their sympatholytic action by decreasing norepinephrine release from presynaptic nerve terminals. Whereas guanethidine and guanadrel interfere with the action potential that triggers norepinephrine release,²²⁴ reserpine depletes norepinephrine, serotonin, and other catecholamines from the presynaptic nerve terminals, probably by direct binding and inactivation of catecholamine storage vesicles.⁸⁴ Adverse events limit their clinical usefulness. These effects include a high incidence of orthostatic and exercise-induced hypotension, diarrhea, increased gastric secretions, and impotence.¹⁷⁹ In addition, this hypotensive effect may be prolonged for as long as one week.^{119,225} Because of its ability to cross the blood–brain barrier, reserpine may also deplete central catecholamines and produce drowsiness, extrapyramidal symptoms, hallucinations, migraine headaches, or depression.¹⁴² In overdose, an extension of their pharmacologic effects is expected. Patients with severe orthostatic hypotension should be anticipated and treated with IV crystalloid boluses and a direct-acting vasopressor. If reserpine is involved, significant CNS depression should also be anticipated.¹⁴²

Peripheral α_1 -Adrenergic Antagonists

The selective α_1 -adrenergic antagonists include prazosin, terazosin, and doxazosin. The α_1 receptor is a postsynaptic receptor primarily located on vascular smooth muscle, although they are also found in the eye and in the GI and genitourinary tracts.^{49,107} In fact, these xenobiotics provide first line pharmacologic therapy for patients with urinary dysfunction secondary to benign prostatic hyperplasia.¹³⁶ They produce arterial smooth muscle relaxation, vasodilation, and a reduction of the blood pressure. Although better tolerated than ganglionic blockers and peripheral adrenergic neuron blockers, they may still produce significant symptoms of postural hypotension, including lightheadedness, syncope, or palpitations, particularly after the first dose or if the dosing is rapidly increased.¹⁷ Hypotension and CNS depression ranging from lethargy to coma are reported in overdose.^{135,140,216} In addition, priapism may occur.^{140,208} Treatment includes supportive care, IV crystalloid boluses, and a vasopressor, with phenylephrine being a logical initial choice.

Direct Vasodilators

Nitroprusside

Hydralazine, Minoxidil, and Diazoxide. These xenobiotics produce vascular smooth muscle relaxation independent of innervation or known pharmacologic receptors.^{60,118,126} This vasodilatory effect has been attributed to stimulation of nitric oxide release from vascular endothelial cells. The nitric oxide then diffuses into the underlying smooth muscle cells, stimulating guanylate cyclase to produce cyclic guanosine monophosphate (cGMP). This second messenger indirectly inhibits calcium entry into the smooth muscle cells, producing vasodilation.²¹⁵ Minoxidil, however, also has direct potassium channel activation effects.^{128,176} It has been proposed that the opening of these adenosine triphosphate linked potassium channels results in potassium influx and cell depolarization, thereby reducing calcium influx and ultimately relaxing vascular smooth muscle.³³

As this vasodilation occurs, the baroreceptor reflexes, which remain intact, produce an increased sympathetic outflow to the myocardium, resulting in an increase in heart rate and contractile force. Typically, these xenobiotics are used therapeutically in patients with severe, refractory hypertension and in conjunction with a β -adrenergic antagonist to diminish reflex tachycardia. Hydralazine, minoxidil, and diazoxide are effective orally, but sodium nitroprusside is only used IV. Minoxidil is also used topically in a 2% solution to promote hair growth, and significant poisoning has occurred in suicidal adults who have ingested this formulation.^{68,160} Diazoxide, although previously used to rapidly reduce blood pressure in hypertensive emergencies, is rarely used for this indication now as a consequence of its poor ability to titrate and its variable, and occasionally profound, hypotensive effect.¹²⁵

Adverse effects associated with daily hydralazine use include several immunologic phenomena such as hemolytic

anemia, vasculitis, acute glomerulonephritis, and most notably a lupuslike syndrome.¹⁹⁶ Minoxidil may cause changes on ECG, both in therapeutic doses and in overdose. Sinus tachycardia, ST segment depression, and T-wave inversion are all reported.^{94,198,232} There also appears to be an association with supratherapeutic doses of minoxidil and left ventricular multifocal, subacute necrosis, and subsequent fibrosis.^{96,97} The significance of either of these changes is unknown; they typically resolve with either continued therapy or as other toxic manifestations resolve.^{94,97,232}

The common toxic manifestations of these xenobiotics in overdose are an extension of their pharmacologic action. Symptoms may include lightheadedness, syncope, palpitations, and nausea.^{3,147} Signs may be isolated to tachycardia alone,^{198,232} flushing, or alterations in mental status, which is related to the degree of hypotension.¹⁶⁰ Based on AAPCC annual poison data, in recent years, the majority of reported exposures to this class of drugs may have involved the topical formulation of minoxidil²⁹ (Chap. 136).

After appropriate GI decontamination, routine supportive care should be performed with special consideration to maintaining adequate mean arterial pressure. If IV crystalloid boluses are insufficient, then a peripherally acting α -adrenergic agonist, such as norepinephrine or phenylephrine, is an appropriate next therapy. Dopamine and epinephrine should be avoided to prevent an exaggerated myocardial response and tachycardia from β -adrenergic stimulation.

Nitroprusside. Sodium nitroprusside is effectively a prodrug, exerting its vasodilatory effects only after its breakdown and the release of nitric oxide. The nitroprusside molecule also contains five cyanide radicals that, although gradually released, occasionally produce cyanide or thiocyanate toxicity.^{178,219} Physiologic methemoglobin can bind the liberated cyanide. The binding capacity of physiologic methemoglobin is about 175 $\mu\text{g/kg}$ of cyanide, corresponding to a little less than 500 $\mu\text{g/kg}$ of infused sodium nitroprusside. These cyanide moieties are rapidly cleared, both by interacting with various sulfhydryl groups in the surrounding tissues and blood and enzymatically in the liver by rhodanese, which couples them to thiosulfate-producing thiocyanate.⁷⁶ This cyanide detoxification process in healthy adults occurs at a rate of about 1 $\mu\text{g/kg/min}$, which corresponds to a sodium nitroprusside infusion rate of 2 $\mu\text{g/kg/min}$.^{51,219} It is limited by the sulfur donor availability, so factors that reduce these stores, such as poor nutrition in infants and toddlers, critical illness, surgery, and diuretic use, place patients at risk for developing cyanide toxicity.^{40,51} The hemolysis associated with cardiopulmonary bypass may place the patient at particular risk because the elevated free hemoglobin may accelerate the release of cyanide from the sodium nitroprusside moiety.⁴⁰ Therefore, depending on the balance of cyanide release (eg, rate of sodium nitroprusside infusion) and the rate of cyanide detoxification (eg, sulfur donor stores), cyanide toxicity may develop within hours. Infusion rates greater than 4 $\mu\text{g/kg/min}$ of nitroprusside for greater than 12 hours may overwhelm the capacity of rhodanese for detoxifying cyanide.²⁰⁷ Signs and symptoms of cyanide toxicity include alteration in mental status; anion gap metabolic acidosis; and in late stages, hemodynamic instability. If cyanide poisoning does occur, then hydroxycobalamin is the current treatment of choice for treatment (Chap. 126).

One method of preventing cyanide toxicity from sodium nitroprusside is to expand the thiosulfate pool available for detoxification by the concomitant administration of sodium thiosulfate.^{51,92,164,219} Dosing of 1 g sodium thiosulfate for every 100 mg of nitroprusside is typically sufficient to prevent cyanide accumulation.²⁰⁷ Unfortunately, the thiocyanate formed may accumulate, particularly in patients with renal insufficiency, and produce thiocyanate toxicity.^{76,219} Simultaneous infusion of thiosulfate does not interfere with the vasodilatory effects of sodium nitroprusside.¹⁰⁴ Needless to say, the potential of sodium nitroprusside to produce cyanide poisoning, in addition to the introduction of other equally effective and rapidly titratable antihypertensives, has greatly reduced its use.

Thiocyanate is almost exclusively renally eliminated, with an elimination half-life of 3 to 7 days. It is postulated that a continuous sodium nitroprusside infusion of 2.5 $\mu\text{g/kg/min}$ in patients with normal renal function could produce thiocyanate toxicity within 7 to 14 days, although it may be as short as 3 to 6 days or as little as 1 $\mu\text{g/kg/min}$ in patients with CKD who are not receiving hemodialysis.²¹⁹ The symptoms of thiocyanate toxicity begin to appear at serum concentrations of 60 $\mu\text{g/mL}$ (1 mmol/L); are very nonspecific; and they may include nausea, vomiting, fatigue, dizziness, confusion, delirium, and seizures.⁷⁶ Thiocyanate toxicity may produce life-threatening effects, such as hemodynamic and intracranial pressure elevation, when serum concentrations are above 200 $\mu\text{g/mL}$.^{51,76,92,249} Anion gap metabolic acidosis and hemodynamic instability do not occur with thiocyanate toxicity. Although cyanide or thiocyanate concentrations are not typically useful in the management of patients with cyanide toxicity, they may be beneficial for monitoring critically ill patients who are at risk of thiocyanate poisoning. Hemodialysis clears thiocyanate from the serum and should be strongly considered in patients with significant clinical manifestations of thiocyanate toxicity.^{64,153,166}

Another therapy used to prevent cyanide toxicity from sodium nitroprusside is a simultaneous infusion of hydroxocobalamin.¹²⁸ Dosing of 25 mg/h has successfully reduced cyanide poisoning in humans.^{48,270} As with thiosulfate, simultaneous infusion of hydroxocobalamin does not interfere with the vasodilatory effects of sodium nitroprusside.¹⁰⁴ Because of the relative higher cost of hydroxocobalamin as well its interactions with some laboratory tests, thiosulfate should remain the mainstay of prophylaxis against sodium nitroprusside-induced cyanide toxicity (Antidotes in Depth: A40 and A41).

Diuretics

Diuretics can be divided into three main groups: (1) the thiazides and related compounds, including hydrochlorothiazide and chlorthalidone, (2) the loop diuretics, including furosemide, bumetanide, and ethacrynic acid, and (3) the potassium-sparing diuretics, including amiloride, triamterene, and spironolactone. Two other groups of diuretics—the carbonic anhydrase inhibitors, such as acetazolamide, and osmotic diuretics (eg, mannitol)—are not used as antihypertensive agents.

The thiazides produce their diuretic effect by inhibition of sodium and chloride reabsorption in the distal convoluted tubule. Loop diuretics, in contrast, inhibit the coupled transport of sodium, potassium, and chloride in the thick ascending limb of the loop of Henle. Although their exact antihypertensive mechanism is unclear, an increased urinary excretion of sodium, potassium, and magnesium results from the use of loop diuretics. Potassium-sparing diuretics act either as aldosterone antagonists, such as spironolactone, or as renal epithelial sodium channel antagonists, such as triamterene, in the late distal tubule and collecting duct.¹¹⁴

The majority of toxicity associated with diuretics is metabolic and occurs during chronic therapy or overuse.²⁶⁴ Hyponatremia develops within the first 2 weeks of initiation of diuretic therapy in more than 67% of susceptible patients, and female sex, old age, and malnourishment are the greatest risk factors.^{8,235} Symptoms of severe hyponatremia (< 120 mEq/L) may include headache, nausea, vomiting, confusion, seizures, or coma (Chap. 19). The osmotic demyelination syndrome, formally known as central pontine myelinolysis, is reported during rapid correction of severe hyponatremia secondary to diuretic abuse.⁴⁶

Other electrolyte abnormalities associated with diuretic use include hypokalemia and hypomagnesemia, which may precipitate ventricular dysrhythmias such as torsade de pointes and sudden death. This is an extremely controversial topic, with several excellent studies providing conflicting results.^{21,77,185,228,230} Although it is unclear how great a risk, if any, diuretic use may be, it remains prudent to monitor and correct the patient's potassium concentration.^{108,228,262} This is particularly important in elderly patients and for those patients who concomitantly use digoxin, in which setting hypokalemia is clearly associated with dysrhythmias (Chap. 65).^{28,240} Potassium-sparing diuretics may cause hyperkalemia, particularly in the setting of renal insufficiency or when combined with other hyperkalemia-producing drugs such as ACEIs.¹¹⁸

Thiazide diuretics are associated with inducing hyperglycemia, particularly in patients with diabetes mellitus. This is a result of depletion of total body potassium stores. Because insulin secretion is dependent on transmembrane potassium fluxes, this decrease in potassium concentration reduces the amount of insulin secreted.¹⁴⁴ This effect is dose dependent and reversible either by potassium supplementation or discontinuation of the thiazide diuretic.^{39,100} This association has led to significant work and discussion about the routine use of thiazide diuretics as first-line antihypertensives in the treatment of uncomplicated patients.^{52,90,166} In addition, thiazides are less well tolerated than any other antihypertensive drug class leading to significant noncompliance.¹⁶⁵

Thiazide diuretics are also associated with inducing hyperuricemia, renal calculi, and gout.^{34,91,93} This is because the renal elimination of uric acid is extremely dependent on intravascular and urinary volume so diuretic-induced volume depletion reduces uric acid filtration and increases its proximal tubule resorption.^{226,238}

Several unusual reactions are associated with thiazide diuretic use, including pancreatitis; cholecystitis; and hematologic abnormalities, such as hypercoagulability, thrombocytopenia, and hemolytic anemia.^{61,63,212,214,252,261}

Despite the widespread use of these xenobiotics, acute overdoses are distinctly rare.¹³⁹ Major signs and symptoms include GI distress, brisk diuresis, possible hypovolemia and electrolyte abnormalities, and altered mental status.¹³⁹ Typically, the diuresis is short lived because of the limited duration of effect and the rapid clearance of the majority of diuretics. Assessment should focus on fluid and electrolyte status, which should be corrected as needed. If hyperkalemia is unexpectedly discovered, either the ingestion of a potassium-sparing xenobiotic or, more likely, an overdose of potassium supplements, which are frequently prescribed in conjunction with thiazide and loop diuretics, should be considered.^{111,112} Altered mental status, including coma, may result from diuretic overdose without evidence of any fluid or electrolyte abnormalities.^{17,18,139,213} Postulated mechanisms include a direct drug effect and induction of transient cerebral ischemia due to hypotension.¹⁸⁰

Angiotensin-Converting Enzyme Inhibitors

ACEIs are among the most widely prescribed antihypertensives. At the time of this writing, there are 10 ACEIs approved by the US FDA for the treatment of hypertension (Table 63–1). In general, they are well absorbed from the GI tract, reaching peak serum concentrations within 1 to 4 hours. Enalapril and ramipril are prodrugs and require hepatic metabolism to produce their active forms. Elimination is primarily via the kidneys.

TABLE 63–1. Antihypertensives and Pharmacologically Related Agents

β -Adrenergic antagonists ([Chap. 62](#))

Calcium channel blockers ([Chap. 61](#))

Sympatholytics (antagonize α -adrenergic vasoconstriction)

Central α_2 -adrenergic agonists

Clonidine, dexmedetomidine, guanabenz,^a guanfacine,^a methyldopa,^a tizanidine

Central imidazoline agonists

Moxonidine, rilmenidine

Ganglionic blockers

Trimethaphana

Peripheral adrenergic neuron antagonists

Guanadrel,^a metyrosine,^a reserpine^a

Peripheral α_1 -adrenergic antagonists

Doxazosin, prazosin, silodosin, terazosin

Diuretics

Thiazides

Bendroflumethiazide,^a chlorthalidone,^a chlorothiazide, hydrochlorothiazide, hydroflumethiazide,^a indapamide, methyclothiazide,^a metolazone, polythiazide,^a trichlormethiazide^a

Loop diuretics

Bumetanide, ethacrynic acid, furosemide, torsemide

Potassium-sparing diuretics

Amiloride, eplerenone, spironolactone, triamterene

Vasodilators

Diazoxide,^a hydralazine, minoxidil,^a nitroprusside

Angiotensin-converting enzyme inhibitor

Benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, spirapril,trandolapril

Angiotensin II receptor blockers

Azilsartan, candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan

Direct renin inhibitors

Aliskiren

^aIncluded for historical reference; use as antihypertensive limited in the United States.

All ACEIs have a common core structure of a 2-methylpropanolol-L-proline moiety.⁸¹ This structure binds directly to the active site of ACE, which is found in the lung and vascular endothelium, preventing the conversion of angiotensin I to angiotensin II. Because angiotensin II is a potent vasoconstrictor and stimulant of aldosterone secretion, vasodilation;

decreased peripheral vascular resistance; decreased blood pressure; increased cardiac output; and a relative increase in renal, cerebral, and coronary blood flow occur.⁸¹ This hypotensive response may be severe in select patients after their initial dose, resulting in syncope and cardiac ischemia.^{42,106} Patients with renovascular-induced hypertension and patients who are hypovolemic from concomitant diuretic use appear to be at greatest risk.¹⁰⁶ Overall, however, these drugs are well tolerated and have a very low incidence of side effects. Some reported adverse effects include rash, dysgeusia, neutropenia, hyperkalemia, chronic cough, and angioedema.^{56,81,246} Because of their interference with the renin–angiotensin system, ACEIs are potential teratogens and should never be used by pregnant women or women of childbearing age.¹³

ACEI-Induced Angioedema. Angioedema is an inflammatory reaction in which there is increased capillary blood flow and permeability, resulting in an increase in interstitial fluid. If this process is confined to the superficial dermis, urticaria develops; if the deeper layers of the dermis or subcutaneous tissue are involved, angioedema results. Angioedema most commonly involves the periorbital, perioral, or oropharyngeal tissues.¹⁹⁹ This swelling may progress rapidly over minutes and result in complete airway obstruction and death.^{80,85,223} The pathogenesis of acquired angioedema involves multiple vasoactive substances, including histamine, prostaglandin D₂, leukotrienes, and bradykinin.¹¹⁰ Because ACE also inactivates bradykinin and substance P, ACE inhibition results in elevations in bradykinin concentrations that appear to be the primary cause of both ACEI angioedema and cough (Fig. 63–1).^{5,113} There is no evidence that the ACEI angioedema phenomenon is immunoglobulin E (IgE) mediated.⁵

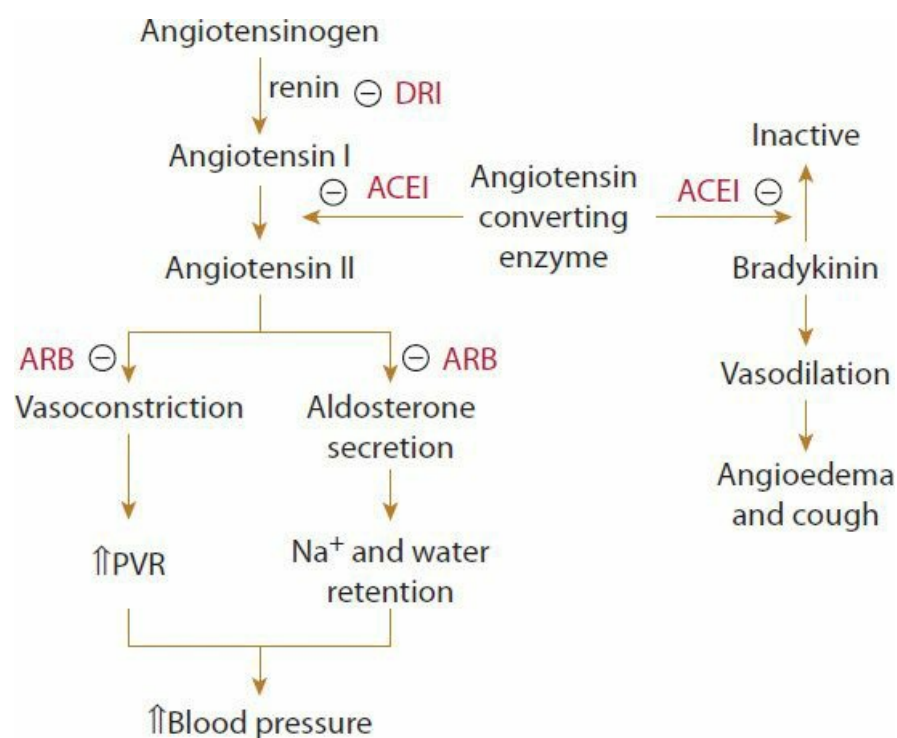

FIGURE 63–1. An overview of the normal function of the renin-angiotensin-aldosterone system (RAAS) and the mechanisms of action of angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), and direct renin inhibitors (DRIs) on that system. PVR = peripheral vascular resistance.

Although the literature is replete with reports of ACEI angioedema, the overall incidence is only approximately 0.1%, and it is idiosyncratic.^{73,113,231} One-third of these reactions occur within hours of the first dose and another third occur within the first week.^{151,231} It is important to remember that the remaining third of cases may occur at any time during therapy, even after years.⁴¹ Women, African Americans, and patients with a history of idiopathic angioedema appear to be at greater risk.^{151,184} In addition, there is evidence that patients who develop ACEI angioedema are at increased subsequent risk of developing angioedema from any etiology.¹⁶

Treatment varies depending on the severity and rapidity of the swelling. Because of its propensity to involve the tongue, face, and oropharynx, the airway must remain the primary focus of management. A nasopharyngeal airway is often helpful. If there is any potential for or suggestion of airway compromise, then endotracheal intubation should be performed. Severe tongue and oropharyngeal swelling may make orotracheal or nasotracheal intubation extremely difficult, if not impossible. If this is a concern, then fiberoptic nasal intubation may be an attractive option, provided that the resources are available. Other techniques, including retrograde intubation over a guidewire that was passed through the cricothyroid membrane and emergent cricothyrotomy, may also be considered.²⁰⁷ However, the most important aspect of airway management in patients experiencing ACEI angioedema is early risk assessment for airway obstruction and rapid intervention before the development of severe and obstructive swelling.²

Because ACEI angioedema is not an IgE-mediated phenomenon pharmacologic therapy targeting an allergic cascade, such as epinephrine, diphenhydramine, and corticosteroids, should not be expected to be effective. However, when the history is unclear, these medications should not be withheld in order to ensure providing life-saving therapy to someone having a severe IgE-mediated allergic reaction.

Newer treatment modalities developed to target various points along the cascade of events associated with hereditary angioedema may be beneficial in the treatment of ACEI angioedema. Hereditary angioedema results from a genetically mediated defect in C1 inhibitor resulting in limited activity of this enzyme and an increase in kallikrein concentrations. Kallikrein is a protease that cleaves kininogen into bradykinin. The end result is very similar to the cause of ACEI angioedema, namely an activation of vascular bradykinin B2 receptors.¹³ Several new treatments have been developed to target specific steps in the development of hereditary angioedema, including Berinert, a C1 esterase inhibitor, ecallantide, a kallikrein inhibitor, and icatibant, a bradykinin B2 receptor antagonist. Case reports of successful treatment of ACEI angioedema with these xenobiotics are few.^{14,79,177} However, one case series of eight patients with ACEI angioedema who were treated with 30 mg subcutaneous icatibant had more rapid improvement in their signs and symptoms as well as no need for subsequent steroid or diphenhydramine use.¹⁴ While further evidence is needed, icatibant may be a reasonable treatment for ACEI angioedema; however, its significant cost should limit its use only in patients with rapidly progressive or severe angioedema.

Fresh frozen plasma (FFP) which contains ACE has also been proposed as treatment for ACEI angioedema. FFP infusion will elevate ACE concentrations and lead to the degradation of accumulated bradykinin. Clinical use of FFP for the successful treatment of both hereditary and ACEI angioedema is reported.^{122,189,200,263} In these case reports, doses range from 1 to 5 units of FFP (200–250 mL/unit) with most using an infusion of 2 units of FFP as initial, and typically definitive, treatment.²⁰⁰

All patients with mild or rapidly resolving angioedema should be observed for several hours to ensure that the swelling does not progress or return. Outpatient therapy with a short course of oral antihistamines and corticosteroids should be considered if there is any question as to whether ACEI therapy produced the angioedema because allergic-mediated angioedema will benefit from this treatment. Patients developing angioedema from ACEI therapy should be instructed to discontinue them permanently and to consult their primary care physicians about other antihypertensive options. Because this is a mechanistic and not allergic adverse effect, the use of any other ACEIs is contraindicated.

Angiotensin-Converting Enzyme Inhibitor Overdose. The toxicity of ACEIs in overdose appears to be limited.^{43,141} Although several reports of overdoses involving ACEIs are published, the majority of the cases reported manifested toxicity of a coingestant.^{54,89,262} Hypotension may occur in select patients,^{11,12,131} but deaths are rarely reported in isolated ACEI ingestions.^{187,235} Other patients may remain asymptomatic despite high serum drug concentrations.¹³¹

Treatment should focus on supportive care and on identifying any coingestants that may be more toxic, particularly other antihypertensives such as β -adrenergic antagonists and calcium channel blockers. In most cases, AC alone is sufficient GI decontamination. IV crystalloid boluses are often effective in correcting hypotension, although in rare cases, catecholamines may be required.^{7,83} Naloxone may also be effective in reversing the hypotensive effects of ACEIs. ACEIs may inhibit the metabolism of enkephalins and potentiate their opioid effects, which include lowering blood pressure.^{57,167} In a controlled human volunteer study, continuous naloxone infusion effectively blunted the hypotensive response of captopril.¹ In one case report, naloxone appeared to be effective in reversing symptomatic hypotension secondary to a captopril overdose.²⁵⁸ In another published case, naloxone was ineffective.¹¹ Although its role in the setting of ACEI overdose remains unclear, naloxone may obviate the need for large quantities of crystalloid or vasopressors and should therefore be considered.

Angiotensin II Receptor Blockers

ARBs were first introduced in 1995, and currently, six members of this class are marketed in the United States. These xenobiotics are rapidly absorbed from the GI tract, reaching peak serum concentrations in 1 to 4 hours, and then are eliminated either unchanged in the feces or after undergoing hepatic metabolism via the mixed function oxidase system eliminated in the bile.^{156–159,181}

Although these xenobiotics are similar to ACEIs in that they decrease the effects of angiotensin II rather than decrease the formation of angiotensin II, they act by antagonizing angiotensin II at the type 1 angiotensin (AT-1) receptor (Fig. 63–1).¹²³ This allows the drugs to inhibit the vasoconstrictive and aldosterone-promoting effects of angiotensin II and reduce blood pressure by blunting both the sympathetic as well as the renin–angiotensin systems.¹⁵⁶ Despite the mechanistic evidence that ARBs do not affect bradykinin degradation and therefore should have a much lower incidence of angioedema when compared to ACEIs, serious cases of angioedema associated with ARB therapy have been reported.^{38,151,255} In addition, there is a significantly higher incidence of angioedema associated with ARBs when compared to other antihypertensives, such as β -adrenergic antagonists.²⁵⁰

Similar to ACEIs, ARBs should never be used by pregnant patients because of their teratogenic potential.^{13,229} In

addition, when initiating the xenobiotic, up to 1% develop of patients first-dose orthostatic hypotension.⁸⁶

There have been few published reports of overdoses involving ARBs. Adverse signs and symptoms reflect orthostatic or absolute hypotension and include palpitations, diaphoresis, dizziness, lethargy, or confusion.^{74,162,233} Hypotension should be treated with crystalloid boluses and catecholamine therapy.^{162,233} Patients who are chronically taking ARBs may exhibit significant hypotension during induction of general anesthesia that has been refractory to traditional vasoconstrictor therapy, such as norepinephrine, ephedrine, and phenylephrine, but appear to respond to vasopressin.^{23,27,67}

One promising new treatment for hypotension produced by ARBs and ACEIs is methylene blue.^{155,171,251} This treatment was first explored in patients placed on cardiopulmonary bypass (CPB).^{186,236,251} During CPB systemic blood pressure and peripheral vascular resistance decrease due to a number of factors, including acute hemodilution, citrate use in the cardioplegia, a poorly defined inflammatory response that results in nitric oxide release, and an increase in circulating bradykinin.^{45,50,268} This increase in bradykinin, which also mediates its vasodilatory effects via nitric oxide, occurs because bradykinin metabolism is primarily in pulmonary tissue and CPB mechanically bypasses the pulmonary system.^{45,50} ACEIs and ARBs exacerbate this vasodilation by inhibiting bradykinin metabolism.¹⁹⁷ In a double blinded placebo controlled study of 30 patients taking ACEIs who were undergoing elective cardiac surgery requiring CPB, administration of methylene blue at the onset of CPB resulted in an increase in mean arterial pressure and systemic vascular resistance and less use of phenylephrine and norepinephrine.¹⁵⁵ A reasonable starting dose of methylene blue, when used as a vasopressor, appears to be 2 mg/kg with subsequent intermittent boluses or possibly continuous infusions starting at 0.5 mg/kg/h.^{115,155}

DIRECT RENIN INHIBITORS

Direct renin inhibitors (DRIs) such as aliskiren exert their antihypertensive effects via the renin-angiotensin-aldosterone system (RAAS) by directly inhibiting circulating renin.²⁶⁵ Unfortunately, all RAAS acting antihypertensives such as ACEIs, ARBs, and DRIs induce a compensatory increase in serum renin concentrations; however, only DRIs are able to blunt the physiologic effects of this rise.^{32,221,265} Aliskiren is well tolerated and is an effective antihypertensive both as monotherapy and in combination with other antihypertensives, including hydrochlorothiazide, calcium channel blockers, and β -adrenergic antagonists.¹⁴⁴ However, significant controversy surrounds aliskiren use when combined ARBs or ACEIs after a clinical trial was halted due to an increased incidence of ischemic stroke, acute kidney injury, hyperkalemia, and hypotension was noted in patients with diabetes and CKD.¹⁸⁸ There are no reported cases of poisoning or overdose; however, hypotension should be anticipated and treatment that includes supportive care, including IV crystalloid and catecholamines, seems reasonable.

SUMMARY

- These xenobiotics are not often associated with severe poisonings, either because of limited use, as with most of the sympatholytics and direct vasodilators, or because of limited toxicity, as with diuretics, ACEIs, ARBs, and DRIs.
- Severe clonidine poisoning classically presents as the opioid toxidrome producing profound CNS depression and bradycardia.
- Clonidine withdrawal manifests as CNS agitation, tachycardia, and hypertension and should be treated with clonidine or benzodiazepines.
- Nitroprusside infusions greater than 4 $\mu\text{g/kg/min}$ may result in cyanide poisoning which can be prevented with coadministration of thiosulfate or hydroxycobalamin.
- Because of the pathogenesis of ACEI-induced angioedema, it is unlikely to respond to “typical” allergic treatment such as antihistamines, epinephrine, and steroids. Rather, focus should be on definitive airway management in patients with rapidly progressing swelling or symptoms.

64 ANTIDYSRHYTHMICS

Lewis S. Nelson

HISTORY AND EPIDEMIOLOGY

The term dysrhythmia encompasses an array of abnormal cardiac rhythms that range in clinical significance from merely annoying to instantly life threatening. Antidysrhythmics include all medications that are used to treat any of these various dysrhythmias. The importance of dysrhythmia management in the modern practice of medicine cannot be overstated, as dysrhythmias are among the most common causes of preventable sudden cardiac death.⁴²

For a long time antidysrhythmics were considered among the most rational of the available cardiac medications. This well-earned reputation related to their high efficacy at reducing the incidence of malignant dysrhythmias. Similarly, they are effective at controlling discomforting rhythm disorders. However, this approach changed dramatically following publication of the Cardiac Arrhythmia Suppression Trials (CAST and CAST II),²³ and, more recently, with the rise of mechanical interventions, such as ablation therapy and implantable defibrillators. CAST assessed the ability of three antidysrhythmics to suppress asymptomatic ventricular dysrhythmias known to be harbingers of sudden death. The original CAST was discontinued in 1989 before completion, when encainide and flecainide, two of the study medications, not only failed to prevent sudden death but actually increased overall mortality. CAST II noted similar problems with moricizine.⁹² It has since become clear that the enhanced mortality associated with many antidysrhythmics is a result of their prodysrhythmogenic effects and that virtually all medications of this group carry such risk. Since patients with atrial fibrillation do not benefit from rhythm conversion compared to control of the ventricular response rate, the use of antidysrhythmics for this indication is now uncommon.⁸⁰

In addition to the predictable, mechanism-based adverse effect of each medication, unique and often unanticipated effects also occur.⁷⁵ Experience with overdose of many of these medications is limited, and management is generally based on the underlying pharmacologic principles, existing case reports, and the experimental literature. This chapter focuses on the medications that serve primarily as antidysrhythmics and, with the exception of lidocaine ([Chap. 67](#)), have few other medicinal indications. [Chapter 16](#) provides a more detailed description of the electrophysiology of dysrhythmias and a discussion of their genesis. In addition, the toxicities from Ca^{2+} channel blockers and β -adrenergic antagonists, which have indications in addition to dysrhythmia control, are discussed separately in [Chaps. 61 and 62](#).

CLASSIFICATION OF ANTIDYSRHYTHMICS

Despite an incomplete understanding of the underlying mechanisms of dysrhythmia formation, an abundance of antidysrhythmics have been developed, each attempting to alter specific electrophysiologic components of the cardiac impulse generating or conducting system.

Antidysrhythmics modify impulse generation and conduction by interacting with various membrane Na^+ , K^+ , and Ca^{2+} channels. Generally, antidysrhythmics manifest electrophysiologic effects either through alteration of the channel pore or, more commonly, by modification of its gating mechanism ([Fig. 62–1](#)). Unfortunately, given their exceedingly complex mechanisms of action, the descriptive terms used to explain their molecular actions are not always completely accurate. For example, the description of an antidysrhythmic as a specific “channel blocker,” although representative of the conceptual action of that medication, is inaccurate because in most cases the molecule does not actually block the channel but rather prevents the channel from opening or closing properly. Furthermore, many of these medications are active nonspecifically at other channels or on other cells, resulting in divergent clinical actions of similarly classified medications.

FIGURE 64–1. Sodium channel blockade. On appropriate signal, Na^+ channel activation occurs, at which time the sodium channel converts from the resting [III] state to the open state [I]. This allows sodium ion influx to initiate phase 0 of the action potential, or cellular depolarization. The sodium channels subsequently assume the inactivated state by closure of an inactivation gate; this is a voltage-dependent phenomena and occurs concomitantly with—although more slowly than—channel activation. Cellular depolarization is maintained for a period of time by other ion channels that form the plateau of the action potential. Prior to reactivating, sodium channels must convert back to the resting state, which also occurs in a voltage-dependent fashion. Many antidysrhythmics stabilize the inactivated state of the channel and, by slowing conversion to the resting state, prevent its reopening, reducing the excitability of the cell. As this is a population phenomena, there are dose-dependent effects on channel blockade; thus, more medication interferes with more channels. Interestingly, certain xenobiotics, such as ciguatoxin and aconitine, stabilize the open state of the sodium channel and produce persistent depolarization.

The Vaughan-Williams classification of antidysrhythmics by electrophysiologic properties emphasizes the connection between the basic electrophysiologic actions and the antidysrhythmic effects.⁹³ Although initially proposed as a descriptive model for electrophysiologic actions and not for clinical effects, the Vaughan-Williams classification is commonly invoked as a user friendly guide to clinical therapy. In 1991, a competing system known as “the Sicilian Gambit” was constructed by a task force of European cardiologists based on the mechanisms by which antidysrhythmics modify dysrhythmogenic mechanisms.⁷⁸ Although perhaps more contemporary in theory, this latter classification system is complex and was therefore never widely implemented. An even more rational classification would match the electrophysiologic effects of the antidysrhythmics with their molecular interactions on different regions of the various ion channels, such as channel gating and pore conductance.

This discussion of antidysrhythmics uses the Vaughan-Williams classification, recognizing the shortcomings delineated above.⁹⁷ The pharmacokinetic properties of the various medications are summarized in [Table 64–1](#).

TABLE 64–1. Antidysrhythmics: Pharmacology, Pharmacokinetics, and Adverse Effects

<i>Antidysrhythmic</i>	<i>Route</i>	<i>Primary Route of Elimination</i>	<i>Elimination $t_{1/2}$</i>	<i>Channel Blockade</i>	<i>Volume Distribution L/Kg</i>	<i>Protein Binding (%)</i>	<i>Adverse Effects and Complicating Factors</i>	<i>Other</i>
Class IA								
Disopyramide	PO	Liver, kidney	5–10 hours	Na ⁺ ($\tau = 9s$), K ⁺ , Ca ²⁺	0.59 ± 0.15	35–95 depending on plasma concentration	CHF, negative inotropic effects, anticholinergic, torsade de pointes, heart block, hypoglycemia	
Procainamide	IV, PO	50%–60% unchanged in kidney; active hepatic metabolite (NAPA)	PA: 3–4 hours ↑ CKD NAPA: 6–10 hours ↑ CKD	Na ⁺ ($\tau = 1.8s$), K ⁺	1.9 ± 0.3	16 ± 9	Hypotension (ganglionic blockade), QRS widening, fever, Lupus-like syndrome, torsade de pointes	NAPA: active metabolite, renally eliminated, K ⁺ channel blocker; $t_{1/2}$ 6–10 hours; sustained-release PA preparation is available
Quinidine	PO	Liver, kidney, 10%–20% unchanged	6–8 hours ↑ liver disease (to >50 hours) and renal failure (to 9–12 hours)	Na ⁺ ($\tau = 3s$), K ⁺ , Ca ²⁺	2.7 ± 1.2	87 ± 3	Heart block, sinus node dysfunction, prolonged QT, hypotension, hypoglycemia, torsade de pointes, thrombocytopenia, ↑ (digoxin)	
Class IB								
Lidocaine	SC, IV, PO (30% BA)	Liver, active metabolite (MEGX, CYP3A4)	8 minutes after bolus 2-hour terminal	Na ⁺ ($\tau = 0.1s$)	1.1 ± 0.4	70 ± 5	Fatigue, agitation, paresthesias, seizures, hallucinations, rarely bundle branch block	Metabolites: GX and MEGX, are less potent as Na ⁺ channel blockers than lidocaine
Mexiletine	IV, PO	Liver (CYP2D6)	10–24 hours	Na ⁺ ($\tau = 0.3s$)	4.9 ± 0.5	63 ± 3	See lidocaine	
Phenytoin	IV, PO	Liver		Na ⁺ ($\tau = 0.2s$)	0.64 ± 0.04	89 ± 23	Hypotension and asystole related to IV propylene glycol infusion, nystagmus, ataxia	
Tocainide	IV, PO	Kidney, liver	9–14 hours	Na ⁺ ($\tau = 0.4s$)	3.0 ± 0.2	10 ± 15	See lidocaine, aplastic anemia, interstitial pneumonia	
Class IC								
Flecainide	IV, PO	Liver (CYP2D6) 75%, kidney 25%	20 hours	Na ⁺ ($\tau = 11s$), Ca ²⁺ , K ⁺	4.9 ± 0.4	61 ± 10	Negative inotropic effects, bradycardia, heart block, ventricular fibrillation, ventricular tachycardia, neutropenia	Two metabolites, one active
Moricizine	PO	Liver	2–4 hours	Na ⁺ ($\tau = 10s$)	?	95	↑ Mortality after myocardial infarction, bradycardia, CHF, ventricular fibrillation, ventricular tachycardia	
Propafenone	IV, PO	Liver (CYP2D6) [extensive first pass]	2–10 hours	Na ⁺ ($\tau = 1s$), K ⁺	3.6 ± 2.1	85 ± 95	Asthma, CHF, hypoglycemia, AV block, QRS prolongation, bradycardia, ventricular fibrillation, ventricular tachycardia	Active metabolite 5-OH-propafenone
Class II								
β-Adrenergic antagonists	IV, PO	Variable	Variable	β-Adrenergic receptor	Variable	Variable	CHF, asthma, hypoglycemia, Raynaud disease	

Class III								
Amiodarone	IV, PO	Liver (100%) (CYP3A4)	2 months	Na ⁺ , K ⁺ , Ca ²⁺	66 ± 44	99.98 ± 0.01	Negative inotropic effects, pulmonary fibrosis, corneal microdeposits, thyroid abnormalities, hepatitis photosensitivity, ↑ diltiazem, quinidine, procainamide, flecainide, digoxin concentrations	Desethylamiodarone has comparable activity to the parent compound
Dofetilide	IV, PO	Kidney	7.5 hours	K ⁺	3.6 ± 0.8	64	Torsade de pointes	Active N-dibutyl metabolite (10%–33% potency)
Dronedarone	PO	Liver (CYP3A4)	13–19 hours	Na ⁺ , K ⁺ , Ca ²⁺	20	>98	Contraindicated in decompensated heart failure, atrial fibrillation that cannot be converted. Liver, thyroid, and pulmonary toxicity (less than amiodarone)	
Ibutilide	IV	Kidney	2–12, average 6 hours	K ⁺ , Na ⁺ opener	11	40	Torsade de pointes, heart block	
Class IV								
Ca ²⁺ channel blockers	IV, PO	Variable	Variable	Ca ²⁺	Variable	Variable	Asystole (if used IV with IV β-adrenergic receptor antagonists), AV block, hypotension, congestive heart failure, constipation, ↑ [digoxin]	
Not classified								
Adenosine	IV	All cells (intracellular adenosine deaminase)	Seconds	Nucleoside-specific G protein-coupled adenosine receptors, ↑ Ca ²⁺ currents activates ACh-sensitive K ⁺ current			Transient asystole < 5 s, chest pain, dyspnea, atrial fibrillation, ↓ BP, effects potentiated by dipyridamole and in heart transplant patients, ↑ dose needed with methylxanthine use	

$\tau_{1/2, \text{Na}^+}$ describes the time it takes for the Na⁺ channel to recover from blockade

AV = antivenetricular; BA = bioavailable; BP = blood pressure; CHF = congestive heart failure; CKD = chronic kidney disease; GI = glycine xylidide; IV = intravenous; NAPA = N-acetylprocainamide; MEGX = monoethylglycidyl ether; PO = oral; SC = subcutaneous.

CLASS I ANTIDYSRHYTHMICS

All antidysrhythmics in Vaughan-Williams class I (A, B, and C) alter Na⁺ conductance through cardiac voltage-gated, fast inward Na⁺ channels (Table 64–1). These medications bind to the Na⁺ channels and slow their recovery from the open or inactivated state to the resting state (Fig. 64–1). This conversion must occur before the channel can reopen and participate in another depolarization. Consequently, as the proportion of medication bound Na⁺ channels increases, fewer of these channels are capable of reactivation on the arrival of the next depolarizing impulse. As a result, by reducing the excitability of the myocardium, abnormal rhythms are both prevented and terminated.

Blockade of these Na⁺ channels slows the rise of phase 0 of the cellular action potential, which correlates with a reduction in the rate of depolarization of the myocardial cell (or V_{max}). Similarly, conduction through the myocardium is slowed, producing a measurable prolongation of the QRS complex on the surface electrocardiogram. Correspondingly, slowed intra-myocardial conduction is associated with reduced contractility, manifesting as negative inotropy. Myocardial depression also results from effects of reduced intracellular Na⁺ on Na⁺-Ca²⁺ exchange.⁶¹ This, in turn, reduces the intracellular Ca²⁺ concentration, which is required for adequate contractility.

The differences among class I antidysrhythmics are directly related to their pharmacologic relationships with the Na⁺

channel. However, it is noteworthy that the original subdivision of class I antidysrhythmics was based on clinical observations, not current pharmacologic awareness, accounting for the somewhat illogical ordering of the class I subdivisions.⁹⁷ Type IB antidysrhythmics have their highest affinity for inactivated Na⁺ channels. This occurs at the end of depolarization, during early repolarization, and during periods of myocardial ischemia, all situations in which the myocardium is partially depolarized. These medications also have rapid “on–off” binding kinetics (rapid τ_{recovery}) and are thus bound only briefly, during late electrical systole, the period during which the Na⁺ channels are predominantly in the inactivated form. They are almost exclusively unbound during electrical diastole, which is the major portion of the cardiac cycle at normal heart rates. However, the degree of binding increases as the heart rate accelerates, because the duration of diastole decreases and the relative proportion of time spent in systole increases; this is termed use dependence. Because all IB antidysrhythmics do not bind to activated Na⁺ channels, in therapeutic doses they do not affect the rate of rise of phase 0 of the action potential, or V_{max} , and have no effect on the electrocardiogram. Alternatively, the class IC antidysrhythmics preferentially act on activated Na⁺ channels or they release from the Na⁺ channels very slowly (slow τ_{recovery}), and, thus, are still bound during the next cardiac cycle. This prolonged channel blockade and reduced channel reactivation result in both greater pharmacologic effects and toxicity, even at slow heart rates. These medications reduce V_{max} and prolong the QRS complex. Class IA antidysrhythmics fall between the other two subclasses.

Although in the Vaughan-Williams classification all class I antidysrhythmics are considered primarily Na⁺ channel blockers, many, particularly those in class IA, have important effects on cardiac K⁺ channels. These channels are critical to maintenance of the cardiac action potential and repolarization of the myocardial cell. Slowing of K⁺ efflux prolongs the duration of the action potential and accounts for the persistence of refractoriness, or the time during which the cell is incapable of repolarization. This effect produces QT prolongation and predisposes to the triggering of polymorphic ventricular tachycardia.⁴³ Because class IB antidysrhythmics have no effect on myocardial K⁺ channels, they do not alter refractoriness or the QT interval. In fact, class IB antidysrhythmics often reduce the action potential duration, shortening refractoriness. Further discussion of K⁺ channel blockade is found in [Chap. 16](#) and in the discussion of class III antidysrhythmics below.

See [Table 64–1](#) for a description of the pharmacokinetics and clinical properties of the various antidysrhythmics.

Class IA Antidysrhythmics: Procainamide, Quinidine, and Disopyramide

Procainamide. Procainamide can be used to suppress either atrial or ventricular tachydysrhythmias. Importantly, procainamide undergoes hepatic biotransformation by acetylation to N-acetylprocainamide (NAPA), the rate of which is genetically determined.⁶⁴ Although NAPA lacks the Na⁺ channel-blocking activity of procainamide, it prolongs the action potential duration through blockade of the K⁺ rectifier currents, and for this reason is available as the class III antidysrhythmic acecainide.³⁸

Rapid intravenous dosing of procainamide is potentially dangerous because its initial volume of distribution is smaller than its final volume of distribution. Because this initial compartment includes the heart, adverse myocardial effects may be unexpectedly pronounced. Thus, to prevent toxicity during medication infusion, the intravenous loading dose is generally administered by slow infusion with electrocardiographic monitoring. Both procainamide and NAPA are renally eliminated and may accumulate in patients with chronic kidney disease (CKD).⁵⁵

Although the chronic use of procainamide is commonly accompanied by the development of antinuclear antibodies or medication-induced systemic lupus erythematosus,³⁹ this syndrome is not associated with acute poisoning. Furthermore, NAPA has less propensity than procainamide to produce this syndrome.³⁸ Other reported adverse effects include seizures and antimuscarinic effects with acute overdose and myopathic pain, thrombocytopenia, and agranulocytosis following long-term use.

Serum concentrations of both procainamide and NAPA serum concentrations should be determined as part of therapeutic drug monitoring (therapeutic: 5–20 $\mu\text{g/mL}$) and in patients with procainamide overdose. Because the elimination half-life of procainamide is 3 to 4 hours, which is substantially shorter than that of NAPA (6–10 hours), chronic overdosing typically results in NAPA toxicity.⁴ In this situation, the QT interval, a reflection of K⁺ channel blockade, correlates directly, and blood pressure correlates inversely, with the degree of poisoning. Severe effects usually do not occur until total (procainamide plus NAPA) serum concentrations are greater than 60 $\mu\text{g/mL}$. Because of its structural similarity with amphetamine, patients with procainamide overdose may have a false-positive urine enzyme-multiplied immunoassay test (EMIT) for amphetamines.⁹⁸

Quinidine. Quinidine, the d-isomer of quinine, is derived from the bark of the cinchona tree. Because it is a weak base, it is typically formulated as the sulfate or gluconate salt. Quinidine undergoes hydroxylation by the liver, and both active and inactive metabolites are renally eliminated.

Quinidine was once widely used for the management of atrial or ventricular dysrhythmias, but has largely fallen out of favor due to its adverse effects. Quinidine has substantial cardiotoxicity that includes intraventricular conduction

abnormalities and an increased QT interval. “Quinidine syncope,” in which patients on therapeutic doses of quinidine experience paroxysmal, transient loss of consciousness, is most frequently a result of torsade de pointes.⁴¹

Because quinidine shares many pharmacologic properties with quinine (Chap. 59), patients may occasionally experience cinchonism following either chronic or acute quinidine overdose. This syndrome includes abdominal symptoms, tinnitus, and altered mental status. Quinidine also produces both peripheral and cardiac antimuscarinic effects, which enhance conduction via the atrioventricular (AV) node. Furthermore, as with quinine, quinidine-induced blockade of K⁺ channels in pancreatic islet cells may cause uncontrolled insulin release, leading to hypoglycemia.⁶⁹

Serum quinidine concentrations greater than 14 µg/mL are associated with cardiotoxicity,⁴⁷ as evidenced by a 50% increase in either the QRS or QT interval.

Disopyramide. Disopyramide (Fig. 64–2) is more likely than other class IA antidysrhythmics to produce negative inotropy and congestive heart failure. This effect may be noted both in patients receiving therapeutic dosing,⁸⁸ and in those who overdose, and may be related to the blockade of myocardial Ca⁺⁺ channels caused by disopyramide. The current use of disopyramide for the treatment of patients with hypertrophic cardiomyopathy capitalize on this clinical effect.²⁵ The mono-N-dealkylated metabolite of disopyramide produces the most pronounced anticholinergic effects of the class,⁹⁵ accounting for the occasional, though unproven, use of disopyramide to treat neurocardiogenic syncope.⁷⁷ Lethargy, confusion, or hallucinations may be prominent in overdose.

FIGURE 64–2. Structures of class IA antidysrhythmics and quinine.

Electrophysiologic abnormalities similar to those associated with poisoning from other class IA antidysrhythmics can occur, including intraventricular conduction abnormalities, torsade de pointes, and other ventricular dysrhythmias. Disopyramide may cause hyperinsulinemic hypoglycemia through its antagonism of K⁺ channels in the pancreatic islet cells.¹

Management of Class IA Antidysrhythmic Toxicity. Management concentrates on assessment and correction of cardiovascular dysfunction. Following airway evaluation and intravenous line placement, 12-lead electrocardiography (ECG) and continuous ECG monitoring are of paramount importance. Appropriate gastrointestinal decontamination is recommended when the patient is sufficiently stabilized and should include whole-bowel irrigation if a sustained-release preparation is involved (Chap. 8 and Antidotes in Depth: A2).

For patients who have widening of the QRS complex duration, bolus administration of intravenous hypertonic sodium bicarbonate is indicated (Antidotes in Depth: A5). Depolarization is accelerated and the QRS complex duration is reduced, by enhancing rapid Na⁺ ion influx through the myocardial Na⁺ channels.⁸ However, hypokalemia from the use of sodium bicarbonate may further prolong the QT interval, requiring careful monitoring of the serum K⁺ and ECG. Class IA

antidysrhythmic-induced hypotension is treated primarily with rapid infusion of 0.9% NaCl to expand intravascular volume and to simultaneously increase myocardial contractility by enhancing the Starling force. Hypotension in the setting of QRS complex duration prolongation may respond favorably to hypertonic sodium bicarbonate, which enhances inotropy by both accelerating depolarization and raising intravascular volume. Dobutamine (an inotrope) or norepinephrine (an inotrope and pressor), and intraaortic balloon pump insertion may also be required, but their use has not been systematically evaluated. Because disopyramide also blocks Ca^{2+} channels, Ca^{2+} administration is reportedly beneficial,² although evidence to support this antidotal effect is lacking. Glucagon effectively reversed myocardial depression in canine models, but it has not been evaluated in humans.⁶³

Patients with stable ventricular dysrhythmias occurring in the setting of class IA antidysrhythmic poisoning are usually treated with hypertonic sodium bicarbonate or lidocaine. Although it may seem counterintuitive to administer another class I antidysrhythmic to a patient already poisoned by a class I antidysrhythmic, there is sound theoretical and experimental literature to support the use of lidocaine in this setting.⁹⁹ Because lidocaine is a class IB antidysrhythmic with rapid on-off receptor kinetics, it may displace the “slower” class IA antidysrhythmic from the binding site on the Na^+ channel, effectively reducing channel blockade. Sodium bicarbonate enhances conduction through the myocardium, promoting spontaneous termination of the ventricular dysrhythmia. Magnesium sulfate and overdrive pacing may be helpful in preventing recurrent torsade de pointes. Medications that must be avoided in treating patients with dysrhythmias associated with class IA poisoning include other class IA and IC antidysrhythmics, as well as the β -adrenergic antagonists and Ca^{2+} channel blockers, all of which may exacerbate conduction abnormalities or produce hypotension.

The roles of charcoal hemoperfusion, hemofiltration, and continuous arteriovenous hemodiafiltration are inadequately defined, but may be most beneficial for removing NAPA.⁵⁵ There is no clinical evidence to support the use of hemodialysis or hemoperfusion for quinidine or disopyramide poisoning.¹

Class IB Antidysrhythmics: Lidocaine, Tocainide, Mexiletine, and Moricizine

Lidocaine. Lidocaine (Fig. 64–3) is an aminoacyl amide that is a synthetic derivative of cocaine. Its predominant clinical uses are as a local anesthetic and, for mechanistically similar reasons, to control ventricular dysrhythmias. The high frequency of lidocaine-related medication errors relates in part to its wide use in the past as well as the availability of “amps” of varying quantities, designed for specific uses such as preparation of intravenous infusions or for local anesthesia.⁴⁴ Lidocaine may prevent myocardial reentry and subsequent dysrhythmia (Chap. 16) by preferentially suppressing conduction in compromised tissue.⁸⁹ Following an intravenous bolus, lidocaine rapidly enters the central nervous system but quickly redistributes into the peripheral tissue with a distribution half-life of approximately 8 minutes.⁹ Lidocaine is 95% dealkylated by hepatic CYP3A4 to an active metabolite, monoethylglycylxylidide (MEGX) and, subsequently, to the inactive glycine xylidide (GX). GX is further metabolized to monoethylglycine and xylidide. MEGX, although less potent as a Na^+ channel blocker than lidocaine, may bioaccumulate because of its substantially longer half-life.⁶

FIGURE 64–3. Structures of the class IB antidysrhythmics lidocaine (and metabolite monoethylglycylxylidide), tocainide, mexiletine, and moricizine.

Patients with massive lidocaine toxicity develop both central nervous system and cardiovascular effects, generally in that order. Because of its rapid entry into the brain, acute lidocaine poisoning typically produces central nervous system dysfunction, with paresthesias or convulsion, as the initial manifestation.^{28,74,84} Concomitant respiratory arrest generally

occurs. Shortly following the central nervous system effects, depression in the intrinsic cardiac pacemakers leads to sinus arrest, AV block, intraventricular conduction delay, hypotension, and/or cardiac arrest. If the patient is supported through this period, then the medication rapidly distributes away from the heart, and spontaneous cardiac function returns.

Acute submassive lidocaine toxicity is generally related to excessive or inappropriate parenteral therapeutic dosing. Common settings include inadvertent intravenous administration instead of the intended route and excessive subcutaneous administration during laceration repair. Acute lidocaine toxicity may occur also with topical tracheal application of lidocaine used for bronchoscopy,¹⁰¹ during circumcision,⁷⁴ as well as ureteral application during ureteroscopic stone extraction.⁶⁶ The typical central nervous system (CNS) manifestations of submassive lidocaine poisoning include drowsiness, weakness, a sensation of “drifting away,” euphoria, diplopia, decreased hearing, paresthesias, muscle fasciculations, and seizures. The more severe of these effects develop when serum lidocaine concentrations exceed 5 µg/mL and are often preceded by paresthesias or somnolence. Therefore, any of these symptoms should prompt the health care professional to examine the patient’s medication administration history or medication-infusion rate. Apnea and seizures, as well as hypotonia in neonates, are reported to result from submassive acute lidocaine toxicity.⁷³

A related form of toxicity and death results from subcutaneous and adipose administration of lidocaine during tumescent liposuction.⁷¹ In this technique, a large volume of dilute lidocaine is used to distend subcutaneous fat prior to liposuction.⁷ Although in some reports the cause of death was controversial,⁷⁰ postmortem lidocaine concentrations were commonly elevated, and it is likely that lidocaine metabolites were also involved in the adverse events.⁴⁵ Interestingly, proponents of this procedure suggest that lidocaine doses up to a maximum of 55 mg/kg are safe,⁷ whereas the conventional recommended limit for subcutaneous lidocaine with epinephrine is only 5 to 7 mg/kg. Of significant concern is that the recommended doses used for liposuction procedures do not consider the ability of lidocaine to saturate the CYP3A4 enzymes. When saturation occurs, elimination lags behind absorption and lidocaine toxicity may result.

Numerous publications unequivocally demonstrate the toxicity associated with orally administered lidocaine despite its poor bioavailability.^{16,102} Some of the toxicity may be due to MEGX. Because of the relatively high concentration of viscous lidocaine (typically 4%), this preparation is overrepresented in reports of oral lidocaine poisoning.¹⁰² As little as 15 mL of 2% viscous lidocaine in a 3 year-old child (estimate, 300 mg or 21.4 mg/kg/dose) may cause seizures.

Chronic lidocaine toxicity most commonly occurs as a result of therapeutic misadventure in patients on lidocaine infusions, generally in a critical care unit. Toxicity following appropriate dosing is most likely to occur in patients with reduced hepatic blood flow as occurs with congestive heart failure, liver disease, or concomitant therapy with CYP3A4 and CYP1A2 inhibitors ([Chap.9](#)).⁹⁴ Adverse reactions to lidocaine also increase with advancing age, decreasing body weight, and increasing infusion rate. Chronic lidocaine toxicity occurs in 6% to 15% of patients receiving infusions at 3 mg/min for several days.⁸² Partly for this reason, lidocaine is no longer routinely used to prevent dysrhythmias in the immediate postmyocardial infarction period. The clearance of lidocaine falls after approximately 24 hours of the start of an infusion, and this effect may be due to competition for hepatic metabolism between lidocaine and its metabolites.

Mexiletine. Mexiletine, originally developed as an anorectic, was found to have antidysrhythmic, local anesthetic, and anticonvulsant activity.¹³ It is currently available in oral form for the management of ventricular dysrhythmias and is also used for the management of chronic neuropathic pain. Its chemical structure and electrophysiologic properties are similar to those of lidocaine. Mexiletine, a base, is absorbed in the small intestine; therefore, its absorption is increased when the gastric contents are alkalinized. Congestive heart failure and cirrhosis, as well as therapy with cimetidine or disulfiram, decrease the clearance of mexiletine.⁵¹ Its metabolism, predominantly through CYP2D6, is accelerated by concomitant use of phenobarbital, rifampin, and phenytoin.

Adverse therapeutic effects are primarily neurologic and are similar to those that occur with lidocaine. The few reported cases of mexiletine overdose describe prominent cardiovascular effects such as complete heart block, torsade de pointes, and asystole.^{18,31} Neurotoxicity resulting from overdose includes self-limited seizures, generally in the setting of cardiotoxicity. Moreover, a single case report described a patient with mexiletine poisoning who experienced status epilepticus without any hemodynamic or electrocardiographic abnormalities.⁶⁰ Mexiletine may produce a false-positive result on the amphetamine immunoassay of the urine.^{18,48}

Moricizine. Moricizine possesses the general qualities of class I antidysrhythmics, but is difficult to specifically subclassify as it has properties that place it in both classes IB or IC.¹⁷ Historically it is discussed as a class IB antidysrhythmic, as it is here. The parent medication undergoes extensive and rapid metabolism. Dose-related lengthening of PR and QRS intervals are expected, as are hemiblocks, bundle blocks, and sustained ventricular tachydysrhythmias. Experience in the setting of myocardial infarction during CAST II suggests that it is a prodysrhythmic.⁹² Clinical experience with overdose is limited, but is expected to be similar to that of other class I antidysrhythmics.

Management of Class IB Antidysrhythmic Toxicity. The focus of the initial management for intravenous lidocaine-induced cardiac arrest is continuous cardiopulmonary resuscitation to allow lidocaine to redistribute away from the heart. Apart from this setting, management of hemodynamic compromise includes fluid replacement and other conventional strategies. Resistant hypotension may require norepinephrine administration, insertion of an intraaortic balloon assist pump,

or bypass.³³ Cardiopulmonary bypass, which does not directly enhance elimination, maintains hepatic perfusion, thereby allowing the lidocaine to be metabolized.³³ Bradydysrhythmias typically do not respond to atropine, requiring the administration of a chronotrope such as norepinephrine or isoproterenol. External pacing or insertion of a transvenous pacemaker may be useful, but the myocardium is often refractory to electrical capture. Lidocaine-induced seizures, and those related to lidocaine analogs, are generally brief in nature and do not require specific therapy. For patients requiring treatment, an intravenous benzodiazepine generally suffices; rarely, a barbiturate is required. Similarly, although intravenous fat emulsion is often described as useful for the resuscitation of patients with life threatening local anesthetic overdose, its use for lidocaine poisoned patients is limited to case reports and likely unnecessary given the rapid time course of recovery (Antidotes in Depth: A20). Enhanced elimination techniques are limited following intravenous poisoning because of the rapid time course of poisoning.³³

Following oral poisoning by a class IB antidysrhythmic, activated charcoal should be administered as appropriate. Lidocaine and its metabolites are not well cleared by hemodialysis,²² and there are no adequate data to support the use of extracorporeal removal for mexiletine or moricizine.

Class IC Antidysrhythmics: Flecainide and Propafenone

Flecainide. Flecainide, a derivative of procainamide, is orally administered to maintain sinus rhythm in patients with structurally normal hearts who have atrial fibrillation or supraventricular tachycardia.⁹⁰ Kidney disease, medication interactions, and congestive heart failure all decrease the clearance of flecainide and its active metabolite. Additionally, alkaluria reduces its clearance, presumably by enhanced tubular reuptake of nonionized medication. Therapeutic doses may produce left ventricular dysfunction with worsening congestive heart failure. This is presumably a result of the negative inotropic effect of flecainide, which itself may relate to its antagonistic effects on Ca^{2+} channels. Furthermore, sudden dysrhythmic death may occur, particularly in patients with underlying ischemic heart disease.⁹⁰

A 50% increase in QRS complex duration, a 30% prolongation of the PR interval, or a 15% prolongation of the QT interval occurs with flecainide toxicity.⁸⁷ The expected consequences of these electrophysiologic disturbances include bradycardia, premature ventricular contractions, and ventricular fibrillation. The combination of marked QRS and PR interval changes, associated with minimal QT interval prolongation, is characteristic of flecainide toxicity and contrasts with those described with other antidysrhythmics.

Propafenone. Propafenone bears a structural resemblance to propranolol,³⁰ as well as similar qualitative, but not quantitative, electrophysiologic properties.²⁷ Propafenone blocks fast inward Na^+ channels, is a weak β -adrenergic antagonist, and is an L-type Ca^{2+} channel blocker.²⁷ Its long half-life allows the accumulation of parent compound, particularly in patients with the slow metabolizer pharmacogenetic variant of CYP2D6, which may cause excessive β -adrenergic antagonism.⁵² Propafenone overdose produces sinus bradycardia, ventricular dysrhythmias, and negative inotropy. The electrocardiogram often shows right bundle-branch block, first-degree AV block, and prolongation of the QT interval. Generalized seizures may also occur.⁶⁵

Management of Class IC Antidysrhythmic Toxicity. Initial stabilization should include standard management strategies for hypotension and seizures. Additionally, therapy for hypotension, and the electrocardiographic manifestations of class IC poisoning, includes intravenous hypertonic sodium bicarbonate to overcome the Na^+ channel blockade.⁶⁰ Several reports of overdose in humans verify QRS complex narrowing in response to hypertonic sodium bicarbonate administration for flecainide^{10,40,54} and propafenone.⁶⁵ Although sodium loading with hypertonic saline may be similarly effective, it remains unproven. The renal elimination of flecainide is reduced by urinary alkalization, suggesting that sodium chloride, in equimolar doses, may ultimately prove superior to sodium bicarbonate.⁵⁸ The administration of other class IC or IA antidysrhythmics is contraindicated because of their additive blockade of the Na^+ channel. Similarly, the administration of phenytoin to a child with propafenone poisoning was associated with a prolongation of the QRS interval, which initially responded to sodium bicarbonate, but the patient subsequently developed bradyasystolic arrest.⁵⁷ However, amiodarone was successful in the setting of flecainide-induced ventricular fibrillation refractory to other therapy.⁸⁵ As with β -adrenergic antagonists, an animal model suggests that hyperinsulinemic euglycemic therapy may be beneficial following propafenone poisoning.¹⁰³ The efficacy of an external or internal pacemaker may be limited because of the medication-induced increased electrical pacing threshold of the ventricle. Successful therapy with cardiopulmonary bypass or extracorporeal membrane oxygenation is reported and should be considered if available.^{5,20} Intravenous fat therapy was reportedly successful in patients with severe flecainide poisoning²⁴ and propafenone poisoning,⁹⁶ although the safety and efficacy of this therapy remain undefined.

Extracorporeal removal is not expected to be beneficial for patients with flecainide poisoning. Although hemodialysis was successful in removing propafenone following overdose, additional studies are needed to determine its clinical benefit.¹¹

CLASS III ANTIDYSRHYTHMICS

Amiodarone, Dofetilide, Dronedarone, and Ibutilide

The class III antidysrhythmics prevent and terminate reentrant dysrhythmias by prolonging the action potential duration and effective refractory period without slowing conduction velocity during phase 0 or 1 of the action potential. This effect on the action potential is generally caused by blockade of the rapidly activating component of the delayed rectifier K^+ current, which is responsible for repolarization.

The class III antidysrhythmics currently used today help prolong repolarization of both the atria and ventricles. Thus, common electrocardiographic effects at therapeutic doses include prolongation of the PR and QT intervals and abnormal T and U waves. Chapter 16 contains a detailed discussion of the pharmacologic mechanisms of class III antidysrhythmics, and Chaps. 16 and 62 discuss sotalol.

Amiodarone and Dronedarone. Amiodarone (Fig. 64–4) is an iodinated benzofuran derivative that is structurally similar to both thyroxine and procainamide. Forty percent of its molecular weight is iodine. Dronedarone is an analog of amiodarone that does not contain iodine.⁴⁹ The 2005 revision of the ACLS guidelines placed tremendous emphasis on the early intravenous administration of amiodarone, and it has retained its prominence in subsequent revisions. Both medications are primarily used to terminate or prevent atrial fibrillation, and, although dronedarone is less effective and has safety issues,¹⁹ it is not associated with many of the potentially severe adverse effects of amiodarone.⁸¹

FIGURE 64–4. Structures of amiodarone (A) compared with triiodothyronine (T₃) (B). Note that amiodarone is nearly 40% iodine by weight.

Although amiodarone and dronedarone have multiple pharmacologic effects, their efficacy is primarily the result of their class III antidysrhythmic effects. They also have weak α - and β -adrenergic antagonist activity and can block both L-type Ca^{2+} channels and inactivated Na^+ channels. Amiodarone is slowly absorbed by the oral route and is concentrated in the liver, lung, and adipose tissue. It has a very long elimination half-life, measured in weeks, and steady-state pharmacokinetics may not occur until after a month of use. Dronedarone has a half-life of about 24 hours and a smaller volume of distribution.

The electrocardiographic effects of amiodarone differ, based on the route of medication administration. Therapeutic oral doses prolong the PR and QT intervals but does not alter the QRS complex. Intravenous dosing may prolong the PR interval, but has few other electrocardiographic manifestations. Ventricular dysrhythmias and sinus bradycardia are the most serious cardiac complications of therapeutic doses of amiodarone. Monomorphic and polymorphic ventricular tachycardias may be resistant to cardioversion and pharmacologic interventions,²⁹ but are surprisingly uncommon given the frequency and extent to which the QT interval prolongation occurs. The ability of amiodarone to compete for P-glycoprotein is responsible for several consequential drug effects, including elevated digoxin and cyclosporin concentrations and enhanced anticoagulation effectiveness of warfarin⁵⁰ (Chap. 9).

The diverse complications associated with long-term amiodarone therapy do not occur following short-term intravenous use. Chronic therapy with oral amiodarone is associated with substantial pulmonary, thyroid, corneal, hepatic, and cutaneous toxicities due to bioaccumulation in these organs. Dronedarone may rarely cause hepatic or pulmonary toxicity.²¹ Many of these effects appear to be dose related, but because of the wide range of bioavailabilities and metabolic patterns among different patients, as well as the overlap between therapeutic and toxic serum concentrations, therapeutic drug monitoring is of limited benefit.³⁵ Pneumonitis, the most consequential extracardiac adverse effect, occurs in up to 5% of patients taking the medication therapeutically. Amiodarone pneumonitis may develop within days of initiating therapy, but typically occurs only after years of therapy. Its occurrence may be dose related: a daily dose of more than 400 mg is a

risk factor, and pneumonitis is rare in those taking less than 200 mg daily. The recent focus on using the minimal effective dose has reduced the incidence of pneumonitis.²⁶ Oxygen supplementation may speed the development of pneumonitis, which may explain the initial belief that patients with chronic lung disease are at increased risk for amiodarone pneumonitis. Manifestations of pneumonitis include dyspnea, cough, hemoptysis, crackles, hypoxia, and radiographic changes.¹⁴ Computed tomography is the most helpful initial diagnostic test for pneumonitis, but is not useful for monitoring purposes, which is often done with diffusing capacity of CO.³⁵ Bronchoalveolar lavage typically reveals interstitial pneumonitis with many macrophages and a characteristic finely vacuolated foamy cytoplasm, but confirmation of the diagnosis requires open lung biopsy.

Thyroid dysfunction, either amiodarone-induced thyrotoxicosis (AIT) or amiodarone-induced hypothyroidism (AIH), occurs in approximately 4% of patients.¹⁵ AIH is more common than AIT when iodine intake is sufficient.³⁵ AIH is likely caused by an exaggerated Wolff-Chaikoff effect, in which iodine, in this case from amiodarone, inhibits the organification and release of thyroid hormone. AIT appears to exist in two distinct forms: type I AIT, which occurs in patients with abnormal thyroid glands and iodine-induced excessive thyroid hormone synthesis and release, and type II AIT, in which destructive thyroiditis leads to release of thyroid hormone from the damaged follicular cells. The relative prevalence of the two forms of AIT is unknown, but it may depend on the ambient iodine intake. Amiodarone may also reduce the effect of thyroid hormone on peripheral tissue. The diagnosis is confirmed with standard thyroid function testing⁹¹ (Chap. 56).

Corneal microdeposits are extremely common during chronic therapy and may lead to vision loss.⁵⁶ Abnormal elevation of hepatic enzymes occurs in more than 30% of those on long-term therapy, and the hepatotoxicity may be associated with progression to cirrhosis. Periodic monitoring of aminotransferases is typically recommended.³⁵ Hepatotoxicity may occur after initial loading of amiodarone.⁷² Slate gray or bluish discoloration of the skin is common, particularly in sun-exposed portions of the body.⁷⁶

Dofetilide. Dofetilide is approved for conversion of atrial fibrillation or atrial flutter to a normal sinus rhythm. Dofetilide increases the effective refractory period more substantially in atrial tissue than in ventricular fibers, accounting for this clinical indication.⁷⁹ Unlike many of the other antidysrhythmics, it may reduce the morbidity of atrial fibrillation in patients with congestive heart failure and is still used despite the emphasis on rate control instead of rhythm control in treating atrial fibrillation. Dofetilide has no known effect on Ca²⁺ or Na⁺ channels, nor does it result in β -adrenergic antagonism. Dofetilide increases the QT interval, but does not change either the PR interval or QRS complex in humans. Heart rate and blood pressure are also not appreciably affected.

Although limited data are available, the expected and reported adverse cardiac events include ventricular tachycardia, particularly torsade de pointes.¹⁰⁰ The approximate incidence of torsade de pointes in patients receiving high therapeutic doses of the medication is 3%.³ For this reason, the US Food and Drug Administration has in place strict requirements for the use of dofetilide, such as an individualized dose initiation algorithm and mandatory hospitalization for initial therapy.⁴⁶

Overdose data reported by the manufacturer include two cases. One patient reportedly ingested 28 capsules and experienced no events, whereas a second patient inadvertently received two supratherapeutic doses one hour apart and experienced fatal ventricular fibrillation after the second dose.⁶⁸ A 33 year-old man ingested 5 mg (20 capsules) and developed QT prolongation within one hour of ingestion, but had no dysrhythmia during his 4-day hospital stay.

Ibutilide. Ibutilide is an antidysrhythmic with predominant class III activity used for the rapid conversion of atrial fibrillation and flutter to normal sinus rhythm. Because of its extensive first-pass metabolism, ibutilide can only be administered parenterally. Its metabolic pathways are not well understood, but do not involve CYP3A4 or CYP2D6. Pharmacokinetic data thus far do not indicate that age, sex, hepatic, or CKD necessitates adjustment of recommended dosage of ibutilide. In addition to its effects on the delayed rectifier current, ibutilide activates a slow inward Na⁺ current.⁵⁹

Ibutilide can increase the QT interval and cause torsade de pointes, especially in patients with congenital long-QT syndrome and in women.³⁶ Although ibutilide can enhance the efficacy of transthoracic cardioversion for atrial fibrillation, its use in patients with ejection fractions below 20% is associated with an increased incidence of sustained polymorphic ventricular tachycardia. Acute kidney injury, including biopsy-identified crystals, is reported in association with ibutilide cardioversion, but a causal relationship is not yet definitive.³² Acute overdose information, only available in limited form (four patients) through the manufacturer, suggests that ventricular dysrhythmias and high-degree AV conduction abnormalities should be expected.⁶⁷

Management of Class III Antidysrhythmic Toxicity

Treatment experience with class III antidysrhythmic overdose is limited. Isoproterenol and overdrive pacing have been used successfully to prevent recurrent torsade de pointes after initial spontaneous resolution or defibrillation.⁸³ Administration of class IB antidysrhythmics or propranolol for the control of monomorphic ventricular tachycardia cannot be recommended on theoretical grounds. Paradoxically, amiodarone may reduce the “torsadogenic” effects of the other

class III antidysrhythmics.⁸⁶ This effect is likely mediated by the beneficial effects of amiodarone on the dispersion of myocardial repolarization and its Ca^{2+} channel-blocking activity.

Multiple-dose activated charcoal may be helpful if used shortly following overdose. Hemodialysis is not expected to be beneficial in general, either because of extensive protein binding or because of large volumes of distribution (Table 64–1). A neonate survived cardiovascular collapse with the use of extracorporeal membrane oxygenation (ECMO) following an iatrogenic intravenous amiodarone overdose.³⁷ Fat emulsion sequesters amiodarone, which may be beneficial in amiodarone toxicity,⁶² but caution should be taken when amiodarone is utilized as a treatment for another poisoning requiring lipid emulsion therapy.

UNCLASSIFIED: ADENOSINE

Adenosine, a nucleoside found in all cells, is released from myocardial cells under physiologic and pathophysiologic conditions. It is administered as a rapid IV bolus to terminate reentrant supraventricular tachycardia. The effects of adenosine are mediated by its interaction with specific G protein-coupled adenosine (A_1) receptors that activate acetylcholine-sensitive outward K^+ current in the atrium, sinus nodes, and AV nodes. The resultant hyperpolarization reduces the rate of cellular firing. Adenosine also reduces the Ca^{2+} currents, and its antidysrhythmic activity results from its effect in increasing AV nodal refractoriness and from inhibiting delayed after depolarizations elicited by sympathetic stimulation.⁵³

Adverse effects of adenosine administration are very common and include transient asystole, dyspnea, chest tightness, flushing, hypotension, and atrial fibrillation. Although bronchospasm occurs following pulmonary vascular administration, it is not reported following routine intravenous use. Dyspnea, and probably chest tightness, is related to adenosine stimulation of the pulmonary vagal C fibers.¹² Fortunately, most of the adverse effects of adenosine are transient because of its rapid metabolism to inosine by both extracellular and intracellular deaminases. The clinical effects are potentiated by dipyridamole, an adenosine uptake inhibitor,³⁴ and by denervation hypersensitivity in cardiac transplant recipients. Methylxanthines may produce adenosine receptor blockade (Chap. 66). In this setting, larger-than-usual doses of adenosine are required to produce an antidysrhythmic effect. Overdose of adenosine is not reported. Treatment is supportive because of the rapid elimination of the medication.

SUMMARY

- In the overdose setting, classes IA, IB, and C antidysrhythmics are all associated with Na^+ channel blockade, which can cause profound wide complex cardiac dysrhythmias and morbidity if not judiciously treated.
- Class IC antidysrhythmics are considerably more toxic than the other class I antidysrhythmics, although even class IB antidysrhythmics may be lethal in overdose. Dysrhythmias are their primary toxicologic effect.
- Class III antidysrhythmics in overdose can cause malignant dysrhythmias, particularly torsade de pointes. Amiodarone has many noncardiac effects, particularly pneumonitis and thyroid effects, which limit its therapeutic usefulness.
- Proper management of both adverse effects and overdose can be accomplished only by understanding the pharmacokinetics and toxicokinetics of these medications.

65 CARDIOACTIVE STEROIDS

Jason B. Hack

HISTORY AND EPIDEMIOLOGY

The Ebers Papyrus provides evidence that the Egyptians used plants containing cardioactive steroids (CASs) at least 3000 years ago. However, it was not until 1785, when William Withering wrote the first systemic account about the effects of the foxglove plant, that the use of CASs was more widely accepted into the Western apothecary. Foxglove, the most common source of plant CAS, was initially used as a diuretic and for the treatment of “dropsy” (edema), and Withering eloquently described its “power over the motion of the heart, to a degree yet unobserved in any other medicine.”¹²⁴

Subsequently, CASs became the mainstay of treatment for congestive heart failure and to control the ventricular response rate in atrial tachydysrhythmias. Because of their narrow therapeutic index and widespread use, both acute and chronic toxicities remain important problems.⁸⁴ According to the American Association of Poison Control Centers data, between the years 2006 and 2011, there were approximately 8000 exposures to CAS-containing plants with one attributable deaths and about 14,500 exposures to CAS-containing xenobiotics resulting in more than 100 deaths (Chap. 136).

Pharmaceutically induced CAS toxicity is typically encountered in the United States from digoxin; other internationally available but much less commonly used preparations are digitoxin, ouabain, lanatoside C, deslanoside, and gitalin. Digoxin toxicity most commonly occurs in patients at the extremes of age or those with chronic kidney disease (CKD). In children, most acute overdoses are unintentional by mistakenly ingesting an adult’s medication, or iatrogenic resulting from decimal point dosing errors (digoxin is prescribed in submilligrams, inviting 10-fold dosing calculation errors), or the elderly who are at risk for digoxin toxicity, most commonly from interactions with another medication in their chronic regimen or indirectly as a consequence of an alteration in the absorption or elimination kinetics. These include drug–drug interactions from an adult’s polypharmacy or from additional acute care xenobiotics that change CAS clearance in the liver or kidney, may alter protein binding and may result in increased bioavailability.

CAS toxicity may also result from exposure to certain plants or animals, including oleander (*Nerium oleander*), yellow oleander (*Thevetia peruviana*), which has been implicated in the suicidal deaths of thousands of patients in Southeast Asia,²⁶ foxglove (*Digitalis* spp), lily of the valley (*Convallaria majalis*), dogbane (*Apocynum cannabinum*), and red squill (*Urginea maritima*). CAS poisoning may result from teas containing seeds of these plants and water and herbal products contaminated with plant CASs (Chap. 45).^{16,19,52,79,90,97,116} Toxicity has resulted from ingestion, instead of the intended topical application, of a purported aphrodisiac derived from the dried secretion of toads from the *Bufo* species, which

contains a bufadienolide-class CAS.^{10,12,13} Although there have been no reported human exposures, fireflies of the Photinus species (*P. ignitus*, *P. marginellus*, and *P. pyralis*) contain the CAS lucibufagin that is structurally a bufadienolides (see Chemistry).^{30,65}

CHEMISTRY

Cardioactive steroids contain an aglycone or “genin” nucleus structure with a steroid core and an unsaturated lactone ring attached at C-17. Cardioactive glycosides contain additional sugar groups attached to C-3. The sugar residues confer increased water solubility and enhance the ability of the molecule to enter cells. Cardenolides are primarily plant-derived aglycons with a five-membered unsaturated lactone ring. The bufadienolide and lucibufagin groups of CAS molecules are mainly animal derived and contain a six-membered unsaturated lactone ring (a plant derived exception is scillaren from red squill). Thus when the aglycone digoxigenin is linked to one or more hydrophilic sugar (digitoxoses) moieties at C-3, it forms digoxin, a cardiac glycoside. The aglycone of digitoxin differs from that of digoxin by the absence of a hydroxyl group on C-12, and ouabain differs from digoxin by both the absence of a hydroxyl group on C-12 and the addition of hydroxyl groups on C-1, C-5, C-10, and C-11. The cardioactive components in toad secretions are genins and lack sugar moieties.

PHARMACOKINETICS

The correlation between clinical effects and serum concentrations is based on steady-state concentrations, which are dependent on absorption, distribution, and elimination (Table 65–1). Although not proven, other CASs likely follow the absorption and distribution pattern of digoxin or digitoxin such that obtaining a serum concentration before 6 hours after ingestion (the time at which tissue concentrations plateau) gives a misleadingly high (predistribution) serum concentration. After therapeutic dosing, the intravascular distribution and elimination of digoxin from the plasma are best described using a two-compartment model that is achieved over approximately 36 to 48 hours in patients with normal kidney function. The distribution or α -phase represents the decrease in intravascular drug concentration and is dependent on whether the route of exposure was intravenous (IV) or oral (PO). Blood concentrations decline exponentially with a distribution half-life of 30 minutes as the drug moves from the blood to the peripheral tissues. Most of the intravascular CAS leaves the blood and distributes to the tissues, resulting in a large volume of distribution (Vd) (eg, the Vd of digoxin is 5–7 L/kg with therapeutic use). The β or elimination phase for digoxin has a half-life of approximately 36 hours and represents the total-body clearance of the drug, which is achieved primarily by the kidneys (70% of its clearance in a person with normal kidney function).^{17,46}

TABLE 65–1. Pharmacology of Selected Cardioactive Steroids

Myocardial irritability causing dysrhythmias

Atrial flutter and atrial fibrillation with atrioventricular (AV) block

Bidirectional ventricular tachycardia

Delayed after-depolarizations

Nonparoxysmal atrial tachydysrhythmias with AV block

Nonsustained ventricular tachycardia

Premature and sustained ventricular contractions

Ventricular bigeminy

Ventricular fibrillation

Primary conduction system dysfunction causing dysrhythmias

Junctional tachycardia

AV dissociation

High degree AV block

Sinus bradycardia

Exit blocks

His-Purkinje dysfunction

Sinoatrial nodal arrest

After a massive acute digoxin overdose, the apparent half-life may be shortened to as little as 13 to 15 hours because elevated serum concentrations result in greater renal clearance before distribution to the tissues.^{51,111} Even with therapeutic administration of CAS, adjustments to the dosing regimen must be made to avert toxicity caused by the physiologic changes associated with aging, including hypothyroidism, chronic hypoxemia with alkalosis, and decreased glomerular filtration rate (GFR). Physiologic changes in CAS kinetics occur with functional decline of the liver, kidney, and heart and dynamics with electrolyte abnormalities, including hypomagnesemia, hypercalcemia, hypernatremia, and commonly hypokalemia. Therefore, serum concentrations should be monitored to avoid inadvertent toxicity. Hypokalemia resulting from a variety of mechanisms, such as the use of loop diuretics, poor dietary intake, diarrhea, and the administration of potassium-binding resins, enhances the effects of CASs on the myocardium and is associated with toxicity at lower serum CAS concentrations. Chronic hypokalemia reduces the number of Na^+ - K^+ -adenosine triphosphatase (ATPase) units in skeletal muscle, which may also alter drug effects.⁶³

Drug interactions between digoxin and quinidine, verapamil, diltiazem, carvedilol, amiodarone, and spironolactone are common.^{20,23,45,68,93} These interactions occur because of a reduction in the protein binding of the CAS, increasing availability to the tissues; a reduction in excretion as a consequence of a decrease in renal perfusion; or, as a result of interference with secretion by the kidneys and intestines, because of inactivation of P-glycoproteins. Also, in approximately 10% to 15% of patients receiving digoxin, a significant amount of digoxin is inactivated in the gastrointestinal (GI) tract by enteric bacterium, primarily *Eubacterium lentum*. Inhibition of this inactivation by the alteration of the GI flora by many antibiotics, particularly macrolides, results in increased bioavailability⁷³ and increased serum CAS concentrations.⁹²

MECHANISMS OF ACTION AND PATHOPHYSIOLOGY

Electrophysiologic Effects on Inotropy

It is currently believed that CASs increase the force of contraction of the heart (positive inotropic effect) by increasing cytosolic Ca^{2+} during systole. Both Na^+ and Ca^{2+} ions enter and exit cardiac muscle cells during each cycle of depolarization and contraction–repolarization and relaxation. Sodium entry heralds the start of the action potential (phase 0) and carries the inward, depolarizing positive charge. Calcium subsequently enters the cardiac myocyte through L-type calcium channels during late phase 0 and the plateau phase of the action potential, and this Ca^{2+} entry triggers the release of Ca^{2+} into the cytosol from the sarcoplasmic reticulum. During repolarization and relaxation (diastole), Ca^{2+} is both pumped back into the sarcoplasmic reticulum by a local Ca^{2+} -ATPase and is moved extracellularly by an Na^+ - Ca^{2+} antiporter (Fig. 65–1; Chap. 17).⁷⁸

FIGURE 65–1. Pharmacology and toxicology of the cardioactive steroids (CASs). (A) Normal depolarization. Depolarization occurs after the opening of fast Na^+ channels; the increase in intracellular potential opens voltage-dependent Ca^{2+} channels, and the influx of Ca^{2+} induces the massive release of Ca^{2+} from the sarcoplasmic reticulum, producing contraction. (B) Normal repolarization. Repolarization begins with active expulsion of 3Na^+ ions in exchange for 2K^+ ions using an ATPase. This electrogenic (3Na^+ for 2K^+) pump creates a Na^+ gradient used to expel Ca^{2+} via an antiporter (NCX). The sarcoplasmic reticulum resequesters its Ca^{2+} load via a separate ATPase. (C) Pharmacologic CAS. Digitalis inhibition of the $\text{Na}^+-\text{K}^+-\text{ATPase}$ raises the intracellular Na^+ content, preventing the antiporter from expelling 1Ca^{2+} in exchange for 3Na^+ . The net result is an elevated intracellular Ca^{2+} , resulting in enhanced inotropy through enhanced SR calcium release. (D) Toxicologic CAS. Excessive elevation of the intracellular Ca^{2+} elevates the resting potential,

producing myocardial sensitization and predisposing to dysrhythmias.

CASs inhibit active transport of Na^+ and K^+ across the cell membrane during repolarization by binding to a specific site on the extracellular face of the α -subunit of the membrane $\text{Na}^+-\text{K}^+-\text{ATPase}$. This inhibits the cellular Na^+ pump activity, which decreases Na^+ extrusion and increases Na^+ in the cytosol, thereby decreasing the transmembrane Na^+ gradient. Because the $\text{Na}^+-\text{Ca}^{2+}$ antiporter derives its power not from adenosine triphosphate (ATP) but rather from the Na^+ gradient generated by the Na^+-K^+ transport mechanism (the antiporter extrudes 1 calcium ion from the cell in exchange for 3 sodium ions moving into the cell down a concentration gradient),²⁹ the dysfunction of the $\text{Na}^+-\text{K}^+-\text{ATPase}$ pump reduces Ca^{2+} extrusion from the cell. The additional cytoplasmic Ca^{2+} enhances the Ca^{2+} -induced Ca^{2+} release from the sarcoplasmic reticulum during systole and by this mechanism increases the force of contraction of the cardiac muscle. Additional mechanisms of action are being explored and include creation of transmembrane calcium channels by cardioactive glycosides.¹

Effects on Cardiac Electrophysiology

At therapeutic serum concentrations, CASs increase automaticity and shorten the repolarization intervals of the atria and ventricles (Table 65–2). There is a concurrent decrease in the rate of depolarization and conduction through the sinoatrial (SA) and atrioventricular (AV) nodes, respectively. This is mediated both indirectly via an enhancement in vagally mediated parasympathetic tone and directly by depression of myocardial tissue. These changes in nodal conduction are reflected on electrocardiography (ECG) by a decrease in ventricular response rate to suprajunctional rhythms and by PR interval prolongation (the latter is part of digitalis effect). The effects of CASs on ventricular repolarization are related to the elevated intracellular resting potential caused by the enhanced availability of Ca^{2+} that manifests on the ECG as QT interval shortening and ST segment and T-wave forces opposite in direction to the major QRS forces. The last effect results in the characteristic scooping of the ST segments (referred to as the digitalis effect; Fig. 65–2).

TABLE 65–2. Electrophysiologic Effects of Cardioactive Steroids on the Myocardium

Any digoxin related life threatening dysrhythmias, regardless of serum digoxin concentration (SDC)

—Includes ventricular tachycardia or ventricular fibrillation, or progressive bradydysrhythmias such as atropine resistant symptomatic sinus bradycardia, or second or third degree heart block.

Potassium concentration > 5 mEq/L in setting of acute digoxin poisoning

Chronic elevation of SDC associated with dysrhythmias, significant gastrointestinal symptoms, or altered mental status

SDC \geq 15 ng/mL at any time or \geq 10 ng/mL 6 hours postingestion, regardless of clinical effects

Acute ingestion of 10 mg of digoxin in an adult

Acute ingestion of 4 mg of digoxin in a child

Poisoning with a nondigoxin cardioactive steroid

Digoxin-specific Fab dosing (round up to number of whole vials in calculation)

$$\begin{aligned}\text{No. of vials} &= \frac{\text{SDC (ng/mL)} \times \text{Patient weight (kg)}}{100} \\ \text{No. of vials} &= \frac{\text{Amount ingested (mg)}}{0.5 \text{ (mg/vial)}} \times 80\% \text{ bioavailability}\end{aligned}$$

Empiric therapy for acute poisoning:

10–20 vials (adult or pediatric {must watch for volume overload})

Empiric therapy for chronic poisoning:

Adults: 3–6 vials

Children: 1–2 vials

FIGURE 65–2. Digitalis effect noted in the lateral precordial lead, V6. Note the prolonged PR interval (long arrow) and the repolarization abnormality (scooping of the ST segment) (short arrow).

Excessive increases in intracellular Ca^{2+} caused by CAS toxicity result in delayed after-depolarizations. These are fluxes in membrane potential caused by spontaneous Ca^{2+} -induced Ca^{2+} release, which is caused by the excess intracellular Ca^{2+} and appear on the ECG as U waves. Occasionally, these may initiate a cellular depolarization that manifests as a premature ventricular contraction (Chap. 16).^{28,60}

Hypokalemia inhibits Na^+ - K^+ -ATPase activity and contributes to the pump inhibition induced by CASs, enhances myocardial automaticity, and increases myocardial susceptibility to CAS-related dysrhythmias. This may be partly a result of decreased competitive inhibition between the CAS and potassium at the Na^+ - K^+ -ATPase exchanger.⁹⁵ Severe hypokalemia (< 2.5 mEq/L) reduces the efficacy of sodium-potassium pump function, slowing the pump and exacerbating concomitant Na^+ - K^+ pump inhibition by CASs.⁶⁰

Effects of Cardioactive Steroids on the Autonomic Nervous System

CASs affect the parasympathetic system by increasing the release of acetylcholine from vagal fibers,^{75,114} possibly through augmentation of intracellular Ca^{2+} . CASs affect the sympathetic system by increasing efferent sympathetic discharge,^{85,109} which may exacerbate dysrhythmias.

CLINICAL MANIFESTATIONS

Although there are differences in the signs and symptoms of acute versus chronic CAS poisoning, adults and children have similar manifestations when poisoned.

Noncardiac Manifestations

Acute Toxicity. An asymptomatic period of several minutes to several hours may follow a single administered toxic dose of CAS. The first effects are typically nausea, vomiting, or abdominal pain. Central nervous system effects of acute toxicity may include lethargy, confusion, and weakness that are not caused by hemodynamic changes.¹⁶ The absence of nausea and vomiting within several hours following exposure makes severe acute CAS poisoning unlikely.

Chronic Toxicity. Chronic toxicity is often difficult to diagnose as a result of its insidious development and protean manifestations, including weakness, anhedonia, and loss of appetite. Symptoms may also include those that occur with acute poisonings; however, they are often less obvious. GI findings include anorexia, nausea, vomiting, abdominal pain, and weight loss. Neuropsychiatric disorders include delirium, confusion, drowsiness, headache, hallucinations, and, rarely, seizures.^{16,38,40} Visual disturbances include transient amblyopia, photophobia, blurring, scotomata, photopsia, decreased visual activity, and aberrations of color vision (chromatopsia), such as yellow halos (xanthopsia) around lights.^{69,70}

Electrolyte Abnormalities. Elevated serum potassium concentrations frequently occur in patients with acute CAS poisoning.^{60,63} Hyperkalemia has important prognostic implications because the serum potassium concentration is a better predictor of lethality than either the initial ECG changes or the serum CAS concentration.^{5,6} In a study of 91 acutely digitoxin poisoned patients conducted before digoxin-specific Fab was available, approximately 50% of the patients with serum potassium concentrations of 5.0 to 5.5 mEq/L died. Although a serum potassium concentration lower than 5.0 mEq/L was associated with no deaths, all 10 patients with serum potassium concentrations above 5.5 mEq/L died.⁵ Elevation of the serum potassium concentration after administration of CASs is a result of CAS inhibition of the Na^+ - K^+ -ATPase pump, which results in the inhibition of potassium uptake in exchange for Na^+ by skeletal muscle (the largest potassium reservoir). Hyperkalemia probably causes further hyperpolarization of myocardial conduction tissue, increasing AV nodal block, thereby exacerbating CAS-induced bradydysrhythmias and conduction delays.⁶⁰ However, correction of the hyperkalemia alone does not increase patient survival⁵; it is a marker for, but not the cause of, the morbidity and mortality associated with

CAS poisoning. Hyperkalemia may also be marker of increased morbidity and subsequent mortality with chronic digoxin overdose.¹²⁶ The interrelationships between intracellular and extracellular potassium and CAS therapy are complex and incompletely understood.

Cardiac Manifestations

General. With therapeutic use, CASs slow tachydysrhythmias without causing hypotension. With poisoning, the alterations in cardiac rate and rhythm may result in nearly any dysrhythmia with the exception of a rapidly conducted supraventricular tachydysrhythmia due to the prominent AV nodal depressive effect of CASs. In 10% to 15% of cases, the first sign of toxicity is the appearance of an ectopic ventricular rhythm.⁹⁴ Although no single dysrhythmia is pathognomonic of CAS toxicity, toxicity should be suspected when there is evidence of increased automaticity in combination with impaired conduction through the SA and AV nodes.⁶⁰ Bidirectional ventricular tachycardia is nearly diagnostic, although it may also occur with poisoning by aconitine and other uncommon xenobiotics¹⁰⁵ (Fig. 16–19). Dysrhythmias, including atrial tachycardia with high-degree AV block, result from the complex electrophysiologic influences on both the myocardium and conduction system of the heart that stem from direct, vagotonic, and other autonomic actions of the CASs.

The effects of digoxin vary with dose and the type of cardiac tissue involved. The atrial and ventricular myocardial tissues exhibit increased automaticity and excitability, resulting in tachydysrhythmias and extrasystoles. In atrial and nodal conducting system tissues, signal velocity is reduced, resulting in an increased PR interval and AV nodal block. AV junctional blocks of varying degrees associated with increased ventricular automaticity are the most common cardiac manifestations, occurring in 30% to 40% of patients with CAS toxicity.⁷⁶ AV dissociation may result from suppression of the dominant pacemaker with escape of a secondary pacemaker or from inappropriate acceleration of a ventricular pacemaker. Hypotension, shock, and cardiovascular collapse may ensue. Table 65–3 summarizes these findings.

TABLE 65–3. Cardiac Dysrhythmias Associated with Cardioactive Steroid Poisoning

Myocardial irritability causing dysrhythmias

Atrial flutter and atrial fibrillation with atrioventricular (AV) block

Bidirectional ventricular tachycardia

Delayed after-depolarizations

Nonparoxysmal atrial tachydysrhythmias with AV block

Nonsustained ventricular tachycardia

Premature and sustained ventricular contractions

Ventricular bigeminy

Ventricular fibrillation

Primary conduction system dysfunction causing dysrhythmias

Junctional tachycardia

AV dissociation

High degree AV block

Sinus bradycardia

Exit blocks

His-Purkinje dysfunction

Sinoatrial nodal arrest

Acute Toxicity. Many cardiac dysrhythmias are associated with CAS toxicity. These dysrhythmias are unified by a sensitized myocardium and a depressed AV node (Table 65–3). The initial bradydysrhythmia results from increased vagal tone at the SA and AV nodes and is often responsive to atropine.

Chronic Toxicity. Bradydysrhythmias that appear later in acute poisonings and with chronic CAS toxicity occur by direct actions on the heart and often are minimally responsive to atropine, if at all. Ventricular tachydysrhythmias are more common in patients with chronic or late acute poisoning.

DIAGNOSTIC TESTING

Properly obtained and interpreted serum digoxin concentrations aid significantly in the management of patients with suspected digoxin toxicity, as well as in the management of patients poisoned by several other CAS. Although most institutions report a therapeutic range for serum digoxin concentration from 0.5 to 2.0 ng/mL (SI units, 1.0–2.6 nmol/mL), current understanding suggests lowering the upper limit to 1.0 ng/mL maintains benefit while decreasing the risk of toxicity.^{98,107} In addition to determining a serum CAS concentration, care must be taken to interpret the concentration as a correlate with the clinical condition of the patient; the interval between the last dose and the time the blood sample was taken; and the presence of other metabolic abnormalities, including hypokalemia, hypomagnesemia, hypercalcemia, hypernatremia, alkalosis, hypothyroidism, and hypoxemia, and the use of xenobiotics such as amiodarone, calcium channel blockers, catecholamines, quinidine, and diuretics.

CAS poisoning is multifactorial and using the upper limit of the therapeutic range of digoxin as the sole indicator of toxicity may be misleading,¹⁰¹ as there is an overlap in serum digoxin concentrations between toxic and nontoxic patients.

In general, a patient's clinical condition and serum concentration correlate well; the significance of a serum concentration depends on when the value is obtained after an acute ingestion to account for the distribution phase of the drug. Asymptomatic patients with CAS concentrations obtained prior to completion of the α distribution, found to be above the therapeutic range, are less often toxic but require close observation and retesting. Patients with mean pharmaceutical CAS serum concentrations above 2 ng/mL for digoxin and above 40 ng/mL for digitoxin measured 6 hours after the last dose often are clinically toxic.⁵⁹ A patient with a markedly elevated CAS concentration at any point after ingestion (eg, ≥ 15 mg/mL) requires definitive therapy.

In most hospitals, "digoxin levels" are the only estimation available to physicians in the acute setting when evaluating a patient for presumed non-digoxin CAS poisoning. The assays typically used in most institutions frequently, but unpredictably, cross-react with other plant- or animal-derived CASs. Although a monoclonal digoxin immunoassay accurately quantifies the serum digoxin concentration, an elevated digoxin concentration in the correct clinical setting may qualitatively assist in making a presumptive diagnosis of nondigoxin CAS exposure (Chaps. 45 and 121).^{14,88} For example, using various techniques, including high-performance liquid chromatography and monoclonal and polyclonal antibody analysis, "digoxin" concentrations were determined from serum to which oleandrin and oleandrogenin from Nerium oleander was added or from patients exposed to Thevetia peruviana (yellow oleander) or toad-secreted bufadienolides.^{10,26,54} Patients with CAS poisoning from plant- or animal-derived CASs may have a positive detection of CAS when using a polyclonal digoxin assay and a low or negative finding when using a monoclonal assay (Chaps. 45 and 121).

Serum concentrations of digoxin are measured in one of two ways: free digoxin and total digoxin. The most common method of quantifying total digoxin in the serum is by fluorescence polarization immunoassay. Under normal circumstances, measuring total digoxin in the serum is sufficient because serum concentrations are predictive of cardiac concentrations.²⁴ However, after the use of digoxin-specific Fab (which remains almost entirely within the intravascular space {Vd, 0.40 L/kg}), there is a large elevation in total CAS concentrations because the CAS is drawn from the tissues and complexes with the antibody fragment, thus trapping the CAS in the intravascular space. When this bulk movement is achieved by binding with Fab fragments, a tremendous increase in total serum digoxin concentrations occurs—representing free plus bound (inactivated) CAS. In this situation, requesting a "free digoxin level" will avoid this spurious increase and reflect clinically relevant unbound digoxin concentration. Paradoxically, excess digoxin Fab may cause a false elevation in digoxin concentration (Chap. 6).

ENDOGENOUS DIGOXINLIKE IMMUNOREACTIVE SUBSTANCE

Some patients have a positive digoxin assay resulting from an endogenous digoxinlike immunoreactive substance (EDLIS) that is structurally and functionally similar to prescribed CASs.⁴⁵ This substance has been found in patients with increased inotropic need or reduced renal clearance, including neonates,¹¹⁷ patients with endstage kidney disease,^{11,41,53} liver disease,⁸¹ subarachnoid hemorrhage,¹²³ congestive heart failure,^{39,102} insulin-dependent diabetes,³⁵ stress,^{40,118} acromegaly,²⁶ or hypothermia,¹¹⁷ after strenuous exercise¹¹⁸ and in pregnancy.^{32,42,50} An endogenous Na⁺-K⁺-ATPase inhibiting dihydropyrone-substituted bufadienolide CAS has been isolated from human placenta.³³ It differs from the toad bufadienolides solely by a single double-bond pyrone ring. Because bufadienolides are not normally found in either healthy humans or edible plants, a synthetic pathway to produce dihydropyrone-substituted steroids in humans may be responsible for EDLIS. Further research is necessary to confirm this pathway.⁵⁰ The clinician suspecting this problem should consult the clinical laboratory.³⁴ Clinical observations indicate that the serum digoxin concentration contributed by EDLIS is usually less than 2 ng/mL. Other endogenous substances, such as bilirubin,⁸¹ and xenobiotics, such as spironolactone,¹⁰³ may also cross-react with the digoxin assay and cause a false-positive result.

THERAPY

Acute Management Overview

Initial treatment of a patient with acute CAS poisoning includes providing general care, (eg, GI decontamination, monitoring for dysrhythmias, measuring electrolyte and digoxin concentrations) and definitive care (eg, administering digoxin-specific antibody fragments). Secondary care includes treating complications such as dysrhythmias and electrolyte abnormalities.

Gastrointestinal Decontamination

The initial treatment should be directed toward prevention of further GI absorption. Rarely, if ever, should emesis or lavage be considered because efficacy is limited due to rapid absorption from the gut and to the emetic effects of the drug itself. Patients with chronic ingestion also do not benefit from these GI decontamination techniques. Because many

CASs, such as digitoxin and digoxin, are recirculated enterohepatically, both late and repeated activated charcoal administration (1 g/kg of body weight every 2–4 hours for up to 4 doses) are beneficial in reducing serum concentrations.^{17,21,67,71,86,121} Activated charcoal prevents reabsorption of CAS from the GI tract and reduces the serum half-life. It should be administered in CAS toxic patients if definitive therapy with digoxin-specific Fab is not immediately available or when renal function is inadequate.²¹

Advanced Management

Digoxin-Specific Antibody Fragments. The definitive therapy for patients with life-threatening dysrhythmias from CAS toxicity (in descending order of associated mortality: ventricular tachycardia, AV junctional tachycardia, AV block¹²⁷) is to administer digoxin-specific antibody fragments.^{2,34,36,87,90,97,106,112,125} Purified digoxin-specific Fab causes a sharp decrease in free serum digoxin concentrations; a concomitant, but clinically unimportant, massive increase in total serum digoxin concentration; an increase in renal clearance of CAS (as a bound drug); and a decrease in the serum potassium concentration.² In addition, the administration of digoxin-specific Fab is pharmacoeconomically advantageous.²² Although the antidote itself is relatively expensive, its expense is far outweighed by obviating the need, risk, and expense of long-term intensive care unit stays and of repetitive evaluation of potassium and digoxin concentrations. [Table 65–4](#) lists the indications for administering digoxin-specific Fab. Extensive discussion is found in Antidotes in Depth: A19.

TABLE 65–4. Indications for Administration of Digoxin-Specific Antibody Fragments (DSFab)

Any digoxin related life threatening dysrhythmias, regardless of serum digoxin concentration (SDC)

—Includes ventricular tachycardia or ventricular fibrillation, or progressive bradydysrhythmias such as atropine resistant symptomatic sinus bradycardia, or second or third degree heart block.

Potassium concentration > 5 mEq/L in setting of acute digoxin poisoning

Chronic elevation of SDC associated with dysrhythmias, significant gastrointestinal symptoms, or altered mental status

SDC ≥ 15 ng/mL at any time or ≥ 10 ng/mL 6 hours postingestion, regardless of clinical effects

Acute ingestion of 10 mg of digoxin in an adult

Acute ingestion of 4 mg of digoxin in a child

Poisoning with a nondigoxin cardioactive steroid

Digoxin-specific Fab dosing (round up to number of whole vials in calculation)

$$\text{No. of vials} = \frac{\text{SDC (ng/mL)} \times \text{Patient weight (kg)}}{100}$$

$$\text{No. of vials} = \frac{\text{Amount ingested (mg)}}{0.5 \text{ (mg/vial)}} \times 80\% \text{ bioavailability}$$

Empiric therapy for acute poisoning:

10–20 vials (adult or pediatric {must watch for volume overload})

Empiric therapy for chronic poisoning:

Adults: 3–6 vials

Children: 1–2 vials

Other Cardiac Therapeutics. Secondary treatments used in patients with symptomatic CAS exposures include the use of atropine for supraventricular bradydysrhythmias or high degrees of AV block. Atropine dosing is 0.5 mg administered IV to an adult or 0.02 mg/kg with a minimum of 0.1 mg to a child. Atropine should be titrated to block the vagotonic effects of CASs. The dose may be repeated at 5-minute intervals if necessary. Therapeutic success is unpredictable because the depressant actions of CASs are mediated only partly through the vagus nerve.

Phenytoin and lidocaine are rarely used (secondary to Fab fragments obviating their utility) for the management of

CAS-induced ventricular tachydysrhythmias and ventricular irritability. These xenobiotics depress the enhanced ventricular automaticity without significantly slowing, and perhaps enhancing, AV nodal conduction.⁹⁶ In fact, phenytoin may reverse digitalis-induced prolongation of AV nodal conduction while suppressing digitalis-induced ectopic tachydysrhythmia without diminishing myocardial contractile forces.⁴⁸ In addition, phenytoin may terminate supraventricular dysrhythmias induced by digitalis more effectively than lidocaine.⁹⁶ Underlying atrial fibrillation and flutter typically do not convert to a normal sinus rhythm with administration of phenytoin or lidocaine. When used, phenytoin should be slowly IV infused (~ 50 mg/min) or in boluses of 100 mg repeated every 5 minutes until control of the dysrhythmias is achieved or a maximum of 1000 mg has been given in adults or 15 to 20 mg/kg in children.^{9,80} Fosphenytoin has not been evaluated in this setting. Maintenance PO doses of phenytoin (300–400 mg/day in adults and 6–10 mg/kg/day in children) should be continued until digoxin toxicity is resolved. Lidocaine is given as a 1- to 1.5-mg/kg IV bolus followed by continuous infusion at 1 to 4 mg/min in adults, or as a 1- to 1.5-mg/kg IV bolus followed by 30 to 50 µg/kg/min in children as required to control the rhythm disturbance ([Chap. 64](#)).

Class IA antidysrhythmics are contraindicated in the setting of CAS poisoning because they may induce or worsen AV nodal block and decrease His-Purkinje conduction at slow heart rates and because their α -adrenergic receptor blockade and vagal inhibition may induce significant hypotension and tachycardia. Class IA antidysrhythmics are also pro-dysrhythmogenic, and their safety in the setting of CAS poisoning is unstudied. Additionally, quinidine reduces renal clearance of digoxin and digitoxin. The use of isoproterenol should be avoided in CAS-induced conduction disturbances because there may be an increased incidence of ventricular ectopic activity in the presence of toxic concentrations of CAS.

Pacemakers and Cardioversion

External or transvenous pacemakers have had limited indications in the management of patients with CAS poisoning. In one retrospective study of 92 digitalis-poisoned patients, 51 patients were treated with cardiac pacing, digoxin-specific Fab, or both; the overall mortality rate was 13%.¹¹³ Prevention of life-threatening dysrhythmias failed in 8% of patients treated with immunotherapy and 23% of patients treated with internal pacemakers. The main reasons for failure of digoxin-specific Fab were pacing-induced dysrhythmias and delayed or insufficient doses of digoxin-specific Fab. Iatrogenic complications of pacing occurred in 36% of patients. Thus, overdrive suppression with a temporary transvenous pacemaker should not be used in the presence of CAS poisoning.^{6,113} In the setting of digoxin poisoning, administration of transthoracic electrical cardioversion for atrial tachydysrhythmias is associated with the development of potentially lethal ventricular dysrhythmias. The dysrhythmias were related to the degree of toxicity and the amount of administered current in cardioversion.⁹⁹ Transthoracic pacing may be attempted for atropine unresponsive bradydysrhythmias in settings where definitive care (digoxin-specific Fab fragments) are delayed or unavailable. In CAS-poisoned patients with unstable rhythms, such as unstable ventricular tachycardia or ventricular fibrillation, cardioversion, and defibrillation, respectively, are indicated.

Electrolyte Therapy

Potassium. Hypokalemia and hyperkalemia may exacerbate CAS cardiotoxicity even at “therapeutic” digoxin concentrations. When hypokalemia is noted in conjunction with tachydysrhythmias or bradydysrhythmias, potassium replacement should be administered with serial monitoring of the serum potassium concentration. Digoxin-specific Fab administration generally should be withheld until the hypokalemia is corrected as the life-threatening manifestations of CAS cardiotoxicity may resolve.

Hyperkalemia may also exacerbate CAS-induced cardiotoxicity, at “therapeutic” digoxin concentrations. Reduction in potassium concentrations should be judiciously initiated with care to avoid hypokalemia. Any exacerbation of CAS cardiotoxicity despite this correction should be treated immediately with Fab fragments.

In acute CAS toxicity, if potassium is at least 5 mEq/L, digoxin-specific antibody fragments are indicated. If digoxin-specific Fab is not available immediately, and ECG evidence of a dysrhythmia suggestive of hyperkalemia is present, an attempt should be made to lower the serum potassium with IV insulin, dextrose, sodium bicarbonate, and PO administration of the ion-exchange resin sodium polystyrene sulfonate as indicated. Caution should be applied to the subsequent administration of digoxin-specific Fab because of concern for profound hypokalemia.

Although calcium is beneficial in most hyperkalemic patients, in the setting of CAS poisoning, administration of calcium salts is considered to be potentially dangerous. A number of experimental studies cite the additive or synergistic actions of calcium and CAS on the heart (because intracellular hypercalcemia is already present), resulting in dysrhythmias,^{37,83,104} cardiac dysfunction⁶¹ (eg, hypercontractility, so-called “stone heart,” hypocontractility), and cardiac arrest.^{72,104,119} Although a 2004 study was unable to show an adverse effect,⁴³ there exist three case reports^{8,64} of CAS-poisoned patients who died at various intervals after calcium administration, which supports the withholding of calcium administration in the setting of hyperkalemia induced by CAS poisoning.

The purported mechanism is augmented intracellular cytoplasmic Ca^{2+} , which results from an increased transmembrane

concentration gradient that further inhibits calcium extrusion through the Na^+ - Ca^{2+} exchange or increased intracytoplasmic stores.⁵⁹ This additional cytoplasmic calcium may result in altered contraction of myofibril organelles,⁶¹ less negative intracellular resting potential that allows delayed afterdepolarizations to reach firing threshold,^{47,59,83} altered function of the sarcoplasmic reticulum,^{61,95} or increased calcium interfering with myocardial mitochondrial function (Chaps. 16 and 17).⁶¹ Although some investigators suspect that the rate of administration of the calcium may be a factor in the subsequent cardiac toxicity,^{72,83} calcium administration should be avoided because better, safer, alternative treatments, such as digoxin-specific Fab, insulin, and sodium bicarbonate, are available for CAS-induced hyperkalemia.^{8,37,64,83,104}

Magnesium. Hypomagnesemia may also occur in CAS-poisoned patients secondary to the contributory factors mentioned with hypokalemia, such as long-term diuretic use to treat congestive heart failure. The theoretical benefits of magnesium therapy in the setting of hypomagnesemia include blockade of the transient inward calcium current, antagonism of calcium at intracellular binding sites, decreased CAS-related ventricular irritability, and blockade of potassium egress from CAS-poisoned cells.^{4,31,55,89,100,110,122} Although hypomagnesemia increases myocardial digoxin uptake and decreases cellular Na^+ - K^+ -ATPase activity, there is conflicting evidence as whether magnesium “reactivates” the CAS-bound Na^+ - K^+ -ATPase activity.^{81,100,110}

A common regimen uses 2 g of magnesium sulfate IV over 20 minutes in adults (25–50 mg/kg/dose to a maximum of 2 g in children). After stabilization, adult patients with severe hypomagnesemia may require a magnesium infusion of 1 to 2 g/h (25–50 mg/kg/h to a maximum of 2 g in children), with serial monitoring of serum magnesium concentrations, telemetry, respiratory rate (observing for bradypnea), deep tendon reflexes (observing for hyporeflexia), and monitoring of blood pressure. Magnesium is contraindicated in the setting of bradycardia or AV block, preexisting hypermagnesemia, and renal insufficiency or failure.

Extracorporeal Removal of Cardioactive Steroids

Forced diuresis,⁶⁶ hemoperfusion,^{77,79,120} and hemodialysis¹²⁰ are ineffective in enhancing the elimination of digoxin because of its large volume of distribution (4–10 L/kg), which makes it relatively inaccessible to these techniques. Because of its high affinity for tissue proteins, approximately 10% of the amount of digoxin is found in the serum than is found at the tissue level, and of that amount, approximately 20% to 40% is protein bound.⁵⁷

SUMMARY

- Digoxin and digitoxin are the most commonly prescribed members of the drugs classified as CASs and they have a narrow therapeutic index.
- Both cardiac and noncardiac effects occur after CAS poisoning, including nausea, vomiting, headache, weakness, altered mental status bradycardia, atrial and ventricular ectopy with block, or hyperkalemia.
- CAS overdose mimics include dysrhythmias from electrolyte abnormalities, primarily hypokalemia, or hypomagnesemia which can be corrected by repletion of potassium or magnesium.
- Definitive therapy for CAS poisoning is the early administration of digoxin-specific Fab immunotherapy coupled with both decontamination techniques including activated charcoal and supportive therapy.

A19 ANTIDOTES IN DEPTH

Digoxin-Specific Antibody Fragments

Mary Ann Howland

INTRODUCTION

Digoxin-specific antibody fragments (DSFab) are indicated for the management of patients with toxicity related to digoxin and digitoxin, as well as oleander, squill, and toad venom, which contain other cardioactive steroids. DSFab have an excellent record of efficacy and safety, and they should be administered early in both established and suspected cardioactive steroid poisoning.

HISTORY

The production of antibody fragments to treat patients poisoned with digoxin followed the development of digoxin antibodies for measuring serum digoxin concentrations by radioimmunoassay (RIA).¹³ This RIA technique permitted the correlation between serum digoxin concentration and clinical digoxin toxicity.^{5,21,27,60}

In 1967, Butler and Chen suggested that purified antidigoxin antibodies with a high affinity and specificity should be developed to treat digoxin toxicity in humans.¹³ The digoxin molecule alone, with a molecular weight of 780 Da, was too small to be immunogenic. But digoxin could function as a hapten when joined to an immunogenic protein carrier such as albumin. These investigators immunized sheep with this conjugate to generate antibodies.^{80,82} The immunized sheep subsequently produced a mixture of antibodies that included antialbumin antibodies and antidigoxin antibodies. The antibodies were separated and highly purified to retain the digoxin antibodies, while removing the antibodies to the albumin and all other extraneous proteins. The antibodies that were developed had a high affinity for digoxin as well as sufficient cross-reactivity with digitoxin and other cardioactive steroids to be clinically useful for the treatment of all cardioactive steroid poisonings.^{15,72,73}

Intact IgG antidigoxin antibodies reversed digoxin toxicity in dogs.¹⁴ Unfortunately, the urinary excretion of digoxin was delayed, and free digoxin was released after antibody degradation occurred. Furthermore, there was significant concern with regard to the development of hypersensitivity reactions. To make such antibodies both safe and effective in humans, whole IgG antidigoxin antibodies were cleaved with papain, yielding two antigen-binding fragments (Fab), with a molecular weight of 50,000 Da each, and one Fc fragment of 50,000 Da.¹⁴ Affinity chromatography is used to isolate and purify the DSFab following papain digestion. Since the Fc fragment does not bind antigen and increases the potential for hypersensitivity reactions, it was eliminated. When compared with whole IgG antibodies, the advantages of DSFab included a larger volume of distribution (Vd), more rapid onset of action, diminished risk of adverse immunologic effects, and more rapid elimination.^{14,48,51,53} In 1976, Digibind was used with clinical success,⁸¹ and it became commercially available in 1986 before being discontinued in 2011.²⁵ Another commercial product, DigiFab, approved by the US Food and Drug Administration (FDA) in 2001, is currently available.²⁶ It is very similar to Digibind, except that it is prepared using a digoxin derivative (digoxin-dicarboxymethoxylamine) as the hapten.

PHARMACOLOGY

Mechanism of Action

Immediately following intravenous (IV) administration, DSFab bind intravascular free digoxin. Uncomplexed antibodies then diffuse into the interstitial space, binding free digoxin there. A concentration gradient is then established, which facilitates movement into the interstitial or intravascular spaces of both the free intracellular digoxin and digoxin that is dissociated from its binding sites on (the external surface of Na⁺-K⁺-adenosine triphosphatase {ATPase} enzyme) in the heart and in skeletal muscle.⁷¹ The dissociation rate constant of digoxin for Na⁺-K⁺-ATPase, therefore, affects the time course for binding to DSFab and, consequently, the onset of action.^{55,75}

The binding affinities of DSFab for digoxin and digitoxin are about 10^9 to 10^{10} M⁻¹ and 10^8 to 10^9 M⁻¹, respectively. They are greater than the affinities of digoxin or digitoxin for the Na⁺-K⁺-ATPase pump receptor.²⁶

Pharmacokinetics

The pharmacokinetics of Digibind and DigiFab (previously named DigiTab) were compared in human volunteers.⁹² Each subject received 1 mg of digoxin intravenously as a 5-minute bolus, followed 2 hours later by a 30-minute IV infusion of 76 mg (an equimolar neutralizing dose) of either Digibind or DigiFab. Free and total digoxin (free plus DSFab bound) were assayed using an ultrafiltration method over 48 hours. At 30 minutes after infusion of either DSFab, the serum free digoxin concentration was below the level of assay detection and remained so for several hours. A few patients in both groups had free digoxin concentrations rebound to peak concentrations of 0.5 ng/mL at approximately 18 hours and the area under the serum drug concentration versus time curve (AUC) for 2 to 48 hours, for free digoxin, was similar for both treatment groups. The elimination half-life of total digoxin averaged 18 hours for DigiFab and 21 hours for Digibind, while the distribution half-life was one hour for each. The volumes of distribution were 0.3 L/kg for DigiFab versus 0.4 L/kg for Digibind.^{25,26} The systemic clearance of DigiFab was higher than Digibind, accounting for the shorter elimination half-life of DigiFab (15 hours versus 23 hours).⁹² Urine sampling over the first 24 hours demonstrated mostly free digoxin and very little free DSFab for both groups. The authors postulated that during renal excretion, the DSFab digoxin complex is metabolized in the kidney by the proximal tubular cells, releasing free digoxin and unmeasured DSFab metabolites.⁹²

Similar findings were described, following the first clinical use of Digibind in a patient who gave a history of ingesting 90 (0.25 mg) digoxin tablets.⁸¹ Total serum digoxin concentration, which was 17.6 ng/mL at the time Digibind infusion was initiated, rose to 226 ng/mL at one hour and remained there for 11 hours, before falling off the next 44 hours, with a half-life of 20 hours.⁸¹ Fab concentrations peaked at the end of the infusion and then apparently exhibited a biphasic or triphasic decline, probably reflecting distribution into different compartments, as well as excretion and catabolism. Free serum digoxin concentrations were undetectable for the first 9 hours, then rose to a peak of 2 ng/mL at 16 hours, and fell to 1.5 ng/mL at both 36 hours and 56 hours, at which time sampling stopped. An analysis of renal elimination based on an incomplete collection suggested that digoxin was excreted only in the bound form during the first 6 hours, but by 30 hours after Fab administration all digoxin in the urine was free digoxin.

A study designed to measure efficacy of DSFab delivery compared a loading dose of DSFab followed by an infusion to the DSFab dose infused over a short amount of time.⁷¹ The former strategy increased the ratio of digoxin bound to uncomplexed DSFab in the serum from 50% to 70%.⁷¹ The authors hypothesized that a very rapid infusion regimen would result in the elimination of DSFab before the fragments could optimally bind the digoxin redistributing from tissue sites.⁷¹

Digoxin takes several hours to distribute from the blood to the tissue compartment. As expected, a rodent model demonstrated that DSFab was more effective when administered prior to complete distribution of digoxin.⁶⁸ Once distribution is complete, increasing the dose of DSFab improved efficacy, as measured by comparing the AUC of digoxin to that of the Fab-digoxin complex.⁶⁸

Pharmacokinetic studies in patients with kidney failure demonstrate that the half-life of DSFab is prolonged 10-fold, with no change in the apparent Vd.⁸⁵ In this situation serum DSFab concentrations remain detectable for 2 to 3 weeks. Total serum digoxin concentrations generally follow DSFab serum concentrations. Case reports demonstrate that free digoxin concentrations reappear up to 10 days following administration of DSFab to patients with severe kidney failure, as compared with 12 to 24 hours in patients with normal kidney function.^{19,28,31,46,57,58,77,79,85–87,93} In one series of patients with end-stage kidney disease, the maximum average concentration of free digoxin was 1.30 ± 0.7 ng/mL and occurred at 127 ± 40 hours.⁸⁷ The mechanism for this rebound is unclear. Following the peak, there is a slow decline that parallels the elimination of DSFab.

Pharmacodynamics

In the multicenter study of 150 patients, the mean time to initial response from the completion of the Digibind infusion (accomplished over 15 minutes to 2 hours) was 19 minutes (range, 0–60 minutes), and the time to complete response was 88 minutes (range, 30–360 minutes).²⁰ Time to response was not affected by age, concurrent cardiac disease, or presence of chronic or acute ingestion.¹

ROLE IN DIGOXIN TOXICITY

A large study evaluating adults and children with acute and chronic digoxin toxicity established the efficacy of Digibind.¹ Of the 150 patients treated, 148 were evaluated for cardiovascular manifestations of toxicity prior to treatment: 79 patients (55%) had high grade atrioventricular block, 68 (46%) had refractory ventricular tachycardia, 49 (33%) had ventricular fibrillation, and 56 (37%) had hyperkalemia. Ninety percent of patients responded within minutes to several hours of

Digibind administration. Complete resolution of all signs and symptoms of digoxin toxicity occurred in 80% of cases. Partial response was observed in 10% of patients, and of the 15 patients who did not respond, 14 were moribund prior to initiation of therapy or later found to not be digoxin toxic. The spectacular success of DSFab is demonstrated by the fact that of the 56 patients who had cardiac arrest caused by digoxin, 54% survived to discharge, as compared with 100% mortality prior to the availability of DSFab.^{1,6} Newborns, infants, and children have all been successfully treated with Digibind.^{6,32,44,76}

ROLE OF DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS WITH OTHER CARDIOACTIVE STEROIDS

DSFab were designed to have high-affinity binding for digoxin and digitoxin. There are structural similarities, however, among all cardioactive steroids. In fact, RIA-determined digoxin concentrations have been reported in patients following poisoning with many nondigoxin cardioactive steroids,^{31,52,61,67} suggesting that there is also cross-reactivity between DSFab and other cardioactive steroids. Thus, DSFab may have variable efficacy for all natural cardioactive steroid poisonings, including those unique cardioactive steroids in oleander, yellow oleander, squill, and toad venom.^{3,11,12,18,30,33,69} In vitro studies also suggest the binding affinity of Digibind for cardioactive steroids.^{22,23,63} However one in vitro study demonstrated cross-reactivity of steroidal alkaloidal compounds in *Veratrum viride* (false hellebore) with the digoxin assay but no binding to DigiFab.⁴ An in vitro study demonstrated that although both Digibind and DigiFab bound digoxin equally well, a small difference in the amount of ouabain binding to Fab subpopulations was identified with twice as much bound to Digibind as DigiFab.⁶⁴

The successful reversal, by Digibind, of cardiotoxicity resulting from ingestion of *Nerium oleander* and *Thevetia peruviana* are reported.^{16,78} One adult and one child each responded to five vials (200 mg) of Fab, but larger doses may be required in other cardioactive steroid poisonings because of the lower affinity binding of Digibind for these toxins. DigiFab is expected to have similar affinity binding toward cardioactive steroids. Both products are polyclonal, contributing to their broad spectrum of affinity for nondigoxin cardioactive steroids. Treatment decisions should be based on empirical grounds, with initial therapy consisting of 10 to 20 vials. Subsequent doses can be based on clinical response.

INDICATIONS FOR DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS

DSFab are indicated for life-threatening, or potentially life-threatening, toxicity from any cardioactive steroid, although the package insert for DigiFab only mentions digoxin.^{25,26} Patients with known or suggestive cardioactive steroid exposure with progressive bradydysrhythmias, including symptomatic sinus bradycardia or second- or third-degree heart block unresponsive to atropine, and patients with severe ventricular dysrhythmias, such as ventricular tachycardia or ventricular fibrillation, should also be treated with DSFab. Ventricular tachycardia with a fascicular block is likely to be a digoxin-toxic rhythm.^{29,52} Any patient with a potassium concentration exceeding 5 mEq/L that is attributable to a cardioactive steroid in the presence of other manifestations of acute or chronic digoxin toxicity should be treated.⁷ Acute ingestions greater than 4 mg in a healthy child (or >0.1 mg/kg), or 10 mg in a healthy adult, may require DSFab, with a lower threshold in compromised patients. Serum digoxin concentrations do not correlate with myocardial concentrations until 4 to 6 hours after ingestion, when an equilibrium from the serum to the myocardium is achieved. Serum concentrations of greater than or equal to 10 ng/mL soon after an acute ingestion may predict the need for treatment with DSFab. Because the elderly are to be at greatest risk of lethality, the threshold for treating patients older than 60 years of age should be lower.⁸ Before the advent of DSFab, mortality in patients older than 60 years of age was 58%, as compared to 8% in patients younger than 40 years of age and 34% in patients between 40 and 50 years of age.⁸ A rapid progression of clinical signs and symptoms, such as cardiac and gastrointestinal toxicity and an elevated or rising potassium concentration, in the presence of an acute overdose, suggests a potentially life-threatening exposure and the need for DSFab.

Cardioactive steroid toxicity causes an increase in intracellular calcium, and the administration of exogenous calcium may further exacerbate conduction abnormalities and potentially result in cardiac arrest, unresponsive to further resuscitation. Thus, in a patient with an unknown exposure who is clinically ill with characteristics suggestive of poisoning by a cardioactive steroid, DSFab should be administered early in the management and always prior to administration of calcium gluconate or chloride. The cardioactive steroid effects can be reversed, obviating the risk associated with the administration of calcium. It may also be difficult to distinguish clinically between digoxin poisoning and intrinsic cardiac disease, which the administration of DSFab can resolve.

A computer-based simulation model compared the treatment of non-life-threatening digoxin toxicity with standard therapy. The authors concluded that treatment with DSFab could decrease length of hospitalization by 1.5 days, a major cost containment benefit.²⁴

ADVERSE EFFECTS AND SAFETY ISSUES

DSFab are generally safe and effective. Reported adverse effects include hypokalemia as a consequence of reactivation of the Na⁺-K⁺-ATPase; withdrawal of the inotropic or atrioventricular nodal blocking effects of digoxin, leading to congestive heart failure or a rapid ventricular rate in patients with atrial fibrillation; and, rarely, allergic reactions.^{25,26} In the multicenter study of 150 patients treated with Digibind, the only acute adverse clinical manifestations were hypokalemia in six patients (4%), worsening of congestive heart failure in four patients (3%), and transient apnea in a neonate who was several hours old.¹ There were no other reactions reported in any of the patients in this series. In a postmarketing surveillance study of Digibind that included 451 patients, two patients with a prior history of allergy to antibiotics reportedly developed rashes.⁶² One of these patients developed a total body rash, facial swelling, and a flush during the infusion. The other experienced a pruritic rash. Two other reported adverse reactions were thrombocytopenia and rigors, and were probably unrelated to the use of Digibind.⁶² One patient received Digibind on three separate occasions over the course of one year for multiple suicide attempts, with no adverse effects.⁹

During the clinical trials with DigiFab, one patient developed pulmonary edema, bilateral pleural effusions, and kidney failure, most likely caused by the loss of the inotropic and chronotropic digoxin effects.²⁶ Phlebitis and postural hypotension were related to the infusion of DigiFab in two healthy volunteers.²⁶

Patients with allergies to papain, chymopapain, or other papaya extracts, or the pineapple enzyme bromelain may be at risk for allergic reactions because trace residues of papaya may remain in the DSFab.^{26,53} Patients with an allergy to sheep protein or those who have previously received ovine antibodies or ovine Fab may also be at risk for allergic reactions, although this is not reported.

PREGNANCY AND LACTATION

DSFab is FDA pregnancy category C. Reproduction studies have not been done, and human case reports are limited. However, considering the maternal benefit of DSFab, it should be used as clinically indicated to protect the maternal fetal dyad. DSFab use should not be withheld because of pregnancy.¹⁰ It is unknown whether DSFab is excreted into breast milk.

DOSING AND ADMINISTRATION

The dose of DSFab depends on the total body load (TBL) of digoxin. Adults and children receiving digoxin therapeutically who develop chronic digoxin toxicity require small doses of DSFab because their total body burden of digoxin is usually small. Children with acute overdoses require DSFab doses based on the amount of digoxin ingested, as in adults.

Estimates of digoxin TBL can be made in three ways: (1) estimate the quantity of digoxin acutely ingested and assume 80% bioavailability (milligrams ingested × 0.8 equals TBL); (2) obtain a serum digoxin concentration and, using a pharmacokinetic formula, incorporate the apparent Vd of digoxin and the patient's body weight (in kilograms); or (3) use an empiric dose based on the average requirements for an acute or chronic overdose in an adult or child.

Each of these methods of estimating the dose of DSFab has limitations. History of ingestion is often unreliable, and empiric doses based on averages may overestimate or underestimate Fab requirements. Using the pharmacokinetic formula assumes a steady-state Vd of 5 L/kg.²⁶ This is not accurate in the acute setting. In addition, the 5 L/kg Vd is a population average that varies with the individual and kidney diseases and hypothyroidism.^{17,94}

Sample calculations for each of these methods are shown in [Tables A19–1, A19–2, and A19–3](#). Each vial contains 40 mg (DigiFab) of purified DSFab that will bind approximately 0.5 mg of digoxin or digitoxin. If the quantity of ingestion cannot be reliably estimated, it is safest to use the largest calculated estimate. The clinician should always be prepared to increase the dose, should symptom resolution be incomplete.

TABLE A19–1. Sample Calculation Based on History of Acute Digoxin Ingestion

Adult

Weight: 70 kg

Ingestion: 50 (0.25-mg) digoxin tablets

Calculation:

$0.25 \text{ mg} \times 50 = 12.5 \text{ mg}$ ingested dose

$12.5 \text{ mg} \times 0.80$ (assume 80% bioavailability) =

10 mg (absorbed dose)

$$\frac{10 \text{ mg}}{0.5 \text{ mg / vial}} = 20 \text{ vials}$$

Child

Weight: 10 kg

Ingestion: 50 (0.25-mg) digoxin tablets

Calculation: Same as for adult. Child will require 20 vials.

TABLE A19-2. Sample Calculations Based on the Serum Digoxin Concentration (SDC)

Adult	Child	Quick Estimation (for Adults and Children)
Weight: 70 kg	Weight: 10 kg	$\text{No. of vials} = \frac{\text{SDC (ng/mL)} \times \text{Patient wt (kg)}}{100} \text{ (Roundup)}$
SDC = 10 ng/mL	SDC: 10 ng/mL	
Volume of distribution = 5 L/kg	Volume of distribution: 5 L/kg	
Calculation*:	Calculation*:	
$\text{No. of vials} = \frac{\text{Total body load (mg)}}{0.5 \text{ mg/vial}}$ $= \frac{\text{SDC} \times V_d \times \text{Patient wt (kg)}}{1000 \times 0.5 \text{ mg/vial}}$	$\text{No. of vials} = \frac{10 \text{ ng/mL} \times 5 \text{ L/kg} \times 10 \text{ kg}}{1000 \times 0.5 \text{ mg/vial}} \text{ (Roundup)}$ $\text{No. of vials} = 1$	
$\text{No. of vials} = \frac{10 \text{ ng/mL} \times 5 \text{ L/kg} \times 70 \text{ kg}}{1000 \times 0.5 \text{ mg/vial}} \text{ (Roundup)}$		
No. of vials = 7		

*1000 is a conversion factor to change ng/mL to mg/L. (Round up) to calculate the number of vials indicated.

TABLE A19-3. Empiric Dosing Recommendations

<i>Acute Ingestion</i>	<i>Chronic Toxicity</i>
Adult: 10–20 vials	Adult: 3–6 vials
Child ^a : 10–20 vials	Child ^b : 1–2 vials

^aMonitor for volume overload in very small children. ^bThe prescribing information contains a table for infants and children, with corresponding serum concentrations.

Each 40 mg vial of DigiFab (which binds 0.5 mg digoxin) should be reconstituted with 4 mL of sterile water for IV injection and gently mixed to provide a solution containing 10 mg/mL of DSFab.²⁶ The reconstituted product should be used promptly or, if refrigerated, it should be used within 4 hours. This preparation can be further diluted with sterile isotonic saline for injection. DigiFab should be administered slowly as an IV infusion over at least 30 minutes unless the patient is critically ill, in which case the DigiFab can be given by IV bolus. If a rate related infusion reaction occurs, the infusion should be stopped, the patient stabilized, and restarted at a slower rate. For infants and small children, the manufacturer recommends diluting the 40-mg vial with 4 mL of sterile water for IV injection and administering the dose undiluted using a tuberculin syringe. For very small doses, this preparation can be further diluted with an additional 36 mL of sterile 0.9% sodium chloride for injection (for a total of 40 mL) to achieve a 1 mg/mL concentration.

MEASUREMENT OF SERUM DIGOXIN CONCENTRATION AFTER DIGOXIN-SPECIFIC ANTIBODY FRAGMENT ADMINISTRATION

Many laboratories are unequipped to determine free serum digoxin concentrations. This is relevant because following DSFab administration, total serum digoxin concentrations are clinically meaningless, as they represent free plus bound digoxin.^{2,25,36,41,49,83} The type of test for total digoxin concentrations used can either result in falsely high or falsely low serum concentrations, depending on which phase (solid or supernatant) is sampled.^{40,54} If the correct dose of DSFab is administered, the free serum digoxin concentrations should be near zero. Free digoxin concentrations begin to reappear 5 to 24 hours or longer after Fab administration, depending on the antibody dose, infusion technique, and the patient's renal function. Newer commercial methods, using ultrafiltration or immunoassays, make free digoxin concentration measurements easier to perform and, therefore, more clinically useful, but they remain associated with errors in the underestimation or overestimation of the free digoxin concentration.^{35,42,59,66,84,88} Free digoxin concentrations are particularly useful in patients with severe kidney dysfunction. Independent of the availability of these data, the patient's cardiac status must be carefully monitored for signs of recurrent toxicity.

Other pitfalls in the measurement and utility of serum digoxin concentrations include endogenous and exogenous factors. Endogenous digoxin-like immunoreactive substances (EDLISs) have been described in infants, in women in the third trimester of pregnancy, and in patients with renal and liver failure.^{34,37,39,43,45,55,89,90} When EDLISs are free or weakly bound, as in these circumstances, they are measurable by the typical RIA and can account for factitiously high reported serum digoxin concentrations in the absence of digoxin treatment. The role of EDLISs in the body has not been fully elucidated, but they have an effect on both the Na⁺-K⁺-ATPase pump and the cardioactive steroid receptor site.³⁸ EDLISs are implicated as a causative factor in hypertension and kidney disease.⁵⁶ Exogenous factors relate primarily to measurement techniques and interpretation.⁴⁷ Digoxin metabolites have varying degrees of cardioactivity.⁵⁰ Some metabolites cross-react and are measured by RIA, while others are not. The in vivo production of these metabolites varies in patients, and may depend on intestinal metabolism by gut flora as well as renal and liver clearance.⁹¹

FORMULATION AND ACQUISITION

DSFab is available as DigiFab. Vials contain 40 mg of purified lyophilized digoxin-immune ovine immunoglobulin fragments 75 mg (approximately) of mannitol USP and 2 mg (approximately) sodium acetate USP as a buffering agent. The diluent is not included. The product contains no preservatives and is intended for IV administration after reconstitution with 4 mL of sterile water for injection USP. Each vial binds 0.5 mg digoxin.

SUMMARY

- Digoxin-specific antibody fragments have dramatically advanced the care and have been lifesaving in patients poisoned with cardioactive steroids.
- In the more than 30 years since the release of DSFab, a potentially lethal overdose of a cardioactive steroid has become manageable, allowing clinicians ease in treatment with minimal risks to patients.

66 METHYLXANTHINES AND SELECTIVE β_2 -ADRENERGIC AGONISTS

Robert J. Hoffman

Caffeine
(1,3,7-trimethylxanthine)

Theophylline
(1,3-dimethylxanthine)

Caffeine

Molecular weight = 194.19 Da
Therapeutic serum concentration = 1–10 $\mu\text{g/mL}$

Theophylline

Molecular weight = 180.17 Da
Therapeutic serum concentration = 5–15 $\mu\text{g/mL}$
= 28–83 $\mu\text{mol/L}$

HISTORY AND EPIDEMIOLOGY

Methylxanthines are plant-derived alkaloids that include caffeine (1,3,7-trimethylxanthine), theobromine (3,7-dimethylxanthine), and theophylline (1,3-dimethylxanthine). They are so named because they are methylated derivatives of xanthine. Members of this group have very similar pharmacologic properties and clinical effects. Methylxanthines are used ubiquitously throughout the world, most commonly in beverages imbibed for their stimulant, mood-elevating, and fatigue-abating effects. *Coffea arabica* and related species are used to make coffee, a beverage rich in caffeine. Cocoa and chocolate are derived from the seeds of *Theobroma cacao*, which contains theobromine and to a lesser extent caffeine. *Thea sinensis*, a bush native to China but now cultivated worldwide, produces leaves from which various teas, rich in caffeine and containing small amounts of theophylline and theobromine, are brewed. *Paullinia* spp, commonly known as guarana, is a South American plant that produces berries with caffeine content much greater than that of coffee beans.

Selective β_2 -adrenergic agonists have been developed for the treatment of bronchoconstriction. Their selectivity has improved therapy for bronchoconstriction, allowing avoidance of the adverse effects of the previously used therapies: epinephrine, an α - and β -adrenergic agonist, as well as isoproterenol, a β_1 - and β_2 -adrenergic agonist. All β_2 -adrenergic agonists have nearly identical clinical effects; the principal differences are their pharmacokinetics. This chapter does not examine each β_2 -adrenergic agonist individually but instead discusses them as a class. The β_2 -adrenergic agonists include albuterol, clenbuterol, bitolterol, formoterol, pirbuterol, salmeterol, terbutaline, and ritodrine.

The American Association of Poison Control Centers (AAPCC) reported the following trends in methylxanthine exposures. Theophylline exposures, which previously caused thousands of poisonings and dozens of deaths annually, have remained rare. From 2007 to 2011, there were 300 to 400 exposures annually, representing how infrequently theophylline is now used therapeutically. Caffeine exposures continue to decrease at a slow and steady rate. In 1998, there were 7390 reported caffeine exposures. This number has steadily declined: from 2007, with 5448 caffeine exposures, to 2011, with

3667 exposures. Caffeine, as a component of energy drinks, has only recently been added to the National Poisoning Data System (NPDS) of the AAPCC. Included as subcategory of poisoning in 2010, there were 308 reported exposures. The following year, the number of reported exposures to caffeine-containing energy drinks increased to 1610 and exposures to caffeine-containing alcoholic beverages was 131.

It is impossible to know the precise reasons, which may be related to underlying patient health as well as differences in toxicity, but the disparity between theophylline deaths and caffeine deaths is notable. The number of deaths resulting from theophylline remains at approximately one or two per year, and even though caffeine poisoning occurred much more frequently, during this same 5-year time period, there was only a single death attributed to caffeine toxicity in the United States.

The number of β_2 -adrenergic agonist exposures has remained stable during the past 5 years, with approximately 8000 to 9000 reports annually and no reported deaths from these substances (Chap. 136).

The overwhelming preponderance of caffeine consumed is in beverages, and a lesser portion is consumed in foods and tablets or capsules. Users typically seek the stimulant effects of caffeine. Caffeine, particularly in herbal forms such as guarana or cola nut, is also increasingly advocated for various health effects.^{15,81} The use of guarana, a plant with very high caffeine content, for weight loss and athletic performance enhancement has become common in recent years. With some scientific evidence demonstrating benefit in athletic performance, caffeine is advocated as a concentration^{110,172} and “energy” booster and as an athletic performance enhancer.^{35,108} High caffeine content products are widely available as dietary supplements, which are not regulated by the Food and Drug Administration (FDA). These include tablets as well as liquid energy “shots.” Energy drinks, which are FDA regulated, typically containing caffeine and other stimulant ingredients are increasingly popular, particularly with adolescents and athletes (Table 66–1).¹³¹

TABLE 66–1. Caffeine and Stimulant Content of Commonly Used Products

Product	Caffeine Content in Typical Single Serving (mg)	Volume of Typical Single Serving (mL)	Other Relevant Beverage Ingredients	Category
Arizona AZ RX Energy Shot	110	240	Niacin, vitamin B ₁₂	Dietary supplement
Caffeine pill (Vivarin, No-Doz)	200	—	—	Medication
Chocolate (Hershey Kiss)	1	—	—	Food
Chocolate milk	10–15	240	Theobromine	Beverage
Coffee (regular)	115–175	330		Beverage
Cola	30	330		Beverage
Espresso	55	30		Beverage
Five-Hour Energy	207	60	Niacin, taurine, vitamin B ₆ , vitamin B ₁₂	Dietary supplement
Hot chocolate	8	240	Theobromine	Beverage
Red Bull	110	250	Taurine	Beverage
Tea (black)	40–100	240	Theobromine, theophylline	Beverage

These drinks have only recently been recognized as having significant adverse side effects.⁸⁵ Although these adverse effects do not routinely result in severe toxicity, major morbidity and mortality have resulted from their use and misuse.⁴ Between 30% and 50% of adolescents and young adults in the United States regularly consume energy drinks.¹⁷³ Surveys of parents in the United States reveal that children as young as 5 years commonly drink caffeinated beverages daily.²⁰¹

Beverages that combine alcohol with relatively large doses of caffeine have rapidly gained popularity, particularly among young adults and underage drinkers. Toxicity from use of such drinks became apparent very soon after these were introduced to the United States.⁴⁵ In some instances, the incidence of toxicity and adverse events associated with such drinks was so significant that some have been legally banned because they are considered exceptionally dangerous. Caffeine has also been recently discovered as a very common adulterant in drug products sold by Internet vendors.⁵⁶ The quantity of caffeine in such products places users at risk for toxicity, although reports of such have not yet surfaced.

Caffeine, theophylline and aminophylline are used in neonates to treat the apnea and bradycardia syndrome of prematurity. The result of such treatment is an increased respiratory rate, decreased apnea, increased cardiac chronotropy and inotropy, and increased cardiac output.³³

Caffeine is used as an analgesic adjuvant, particularly when combined with analgesics such as acetaminophen, aspirin, and ibuprofen.⁵⁹

Theophylline or its water-soluble salt, aminophylline, is used to treat varied respiratory conditions but is most well studied for its use in reversible bronchospastic airway disease, particularly asthma. Theophylline was once the mainstay of therapy for such diseases, but albuterol and other selective β_2 -adrenergic agonists with fewer adverse effects are now used.

Caffeine toxicity is generally classified as acute, acute on chronic, or chronic in nature. Neonates receiving caffeine therapy may develop acute or chronic caffeine toxicity.^{7,17}

Chronic toxicity from caffeine is most typically results from frequent self-administration of excessive caffeine. The Diagnostic and Statistical Manual of Mental Disorders, 4th edition, text revision, notes five distinct caffeine-related disorders, acute toxicity, withdrawal, caffeine-related anxiety disorder, insomnia, and effects not otherwise specified.⁶³ Classically, a syndrome associated with chronic caffeine use consisting of headache, palpitations, tachycardia, insomnia, and delirium has been termed caffeinism.

Theophylline toxicity results from the use of theophylline as a medicinal and may develop as acute, chronic, or acute-on-chronic toxicity.

Acute-on-chronic toxicity may occur with caffeine or theophylline and is the circumstance of acute overdose in a patient already receiving chronic therapy.

Most reported cases of theobromine poisoning occur in the veterinary literature and typically result from small animals ingesting cocoa or chocolate.^{61,90} Theobromine has become an ingredient of numerous “energy” drinks used for stimulation and athletic enhancement, but human toxicity has not yet been reported.

Use of β_2 -adrenergic agonists is widespread. Adverse effects are associated with both therapeutic dosing and overdose. Excessive use of β_2 -adrenergic agonists may result in tachyphylaxis, a phenomenon in which downregulation of receptors occurs and the effects of the drug diminish as a result of excessive use.^{48,104} Consequently, patients may require higher doses to achieve the same clinical effects previously experienced at lower doses, resulting in consequential adverse effects. The most common selective β_2 -adrenergic agonist toxicity results from children ingesting albuterol syrup. The toxicity associated with terbutaline and ritodrine is infrequently reported. Clenbuterol, a long-acting β_2 agonist adrenergic, used for the purpose of treating bronchoconstriction in countries outside the United States, has in recent years emerged as an abused anabolic xenobiotic as well as additive in street drugs. Epidemic clenbuterol exposures have occurred in recent years, as a result of both its admixture with illicit xenobiotics and its intentional use for bodybuilding purposes in the United States.⁵⁵ Food poisoning by consumption of animal meat from livestock treated with clenbuterol has occurred in Europe.¹⁸

PHARMACOLOGY

Methylxanthines

Methylxanthines cause the release of endogenous catecholamines, resulting in stimulation of β_1 and β_2 receptors.¹⁹⁷

Endogenous catecholamine concentrations are extremely elevated in patients with methylxanthine poisoning.²²

Methylxanthines are structural analogs of adenosine and function pharmacologically as adenosine antagonists. Adenosine modulates histamine release and causes bronchoconstriction, which may explain the primary therapeutic efficacy of adenosine antagonists in the treatment of bronchospasm. Additionally, adenosine antagonism results in release of norepinephrine, and to a lesser extent epinephrine, through blockade of presynaptic A_2 receptors. The additional methyl group possessed by caffeine (1,3,7-trimethylxanthine) permits greater central nervous system (CNS) penetration relative to theophylline and theobromine, which are dimethylxanthines. Caffeine is an effective analgesic adjuvant, possibly because of the stimulant properties of the drug.^{138,140,170,171}

Methylxanthines also inhibit phosphodiesterase, the enzyme responsible for degradation of intracellular cyclic AMP (cAMP), which has many effects, including an increase in intracellular calcium concentrations. Phosphodiesterase inhibition was long considered to be the primary therapeutic mechanism of the methylxanthines, but clinically significant elevations in cAMP concentrations are not achieved until serum methylxanthine concentrations are well above the therapeutic range. This likely occurs as a result of the structural similarity of the adenosine moiety of cAMP and the methylxanthines. cAMP is involved in the postsynaptic second messenger system of β -adrenergic stimulation. Thus, elevated cAMP concentrations cause clinical effects similar to adrenergic stimulation, including smooth muscle relaxation, peripheral vasodilation, myocardial stimulation, skeletal muscle contractility, and CNS excitation.

Selective β_2 -Adrenergic Agonists

Selective β_2 -adrenergic agonists act very specifically at β_2 -adrenergic receptors, resulting in an increase in intracellular

cAMP. Effects of β_2 agonism include relaxation of vascular, bronchial, and uterine smooth muscle; glycogenolysis in skeletal muscle; and hepatic glycogenolysis and gluconeogenesis. Selective β_2 -adrenergic agonists have been characterized as directly activating the β_2 receptor, such as albuterol; being taken up into a membrane depot, such as formoterol; or interacting with a receptor-specific auxiliary binding site, such as salmeterol. These differences do not appear to be relevant in acute toxicity.⁹⁹ However, emerging evidence suggests that prolonged overuse of long-acting β_2 -adrenergic agonists may have severe or fatal adverse effects.¹⁶⁸

PHARMACOKINETICS AND TOXICOKINETICS

Caffeine Pharmacokinetics

Caffeine is bioavailable by oral (PO), intravenous (IV), subcutaneous, intramuscular, and rectal routes of administration. PO administration, which is by far the most common route of exposure, results in nearly 100% bioavailability. The presence of food in the gut does little to affect peak concentration. However, food in the gut delays the time until the peak serum concentration is reached, which is typically 30 to 60 minutes in the absence of food. Caffeine rapidly diffuses into the total body water and all tissues and readily crosses the blood–brain barrier and into the placenta. The volume of distribution (Vd) is 0.6 L/kg, and 36% is protein bound. Caffeine is secreted in breast milk with concentrations of 2 to 4 $\mu\text{g/mL}$ in breast milk after 100 mg PO dosing in a breastfeeding mother.¹⁹⁰ Consumption of caffeine does not result in clinically relevant breast milk caffeine concentrations in lactating women or toxicity in their breastfeeding children. Breast milk caffeine concentrations are lower than maternal serum caffeine concentrations, with breast milk having 0.006% to 1.5% of the quantity of maternal serum.²³

When taken in amounts that produce serum caffeine concentrations exceeding a therapeutic range, or approximately 20 mg/kg, caffeine exhibits Michaelis-Menten kinetics and is metabolized, primarily by CYP1A2. The major pathway involves demethylation to 1,7-dimethylxanthine (paraxanthine) followed by hydroxylation or repeated demethylation followed by hydroxylation. To a lesser extent, caffeine is also metabolized to theobromine and theophylline. Neonates demethylate caffeine, producing theophylline, and possess the unique ability to convert theophylline to caffeine by methylation.^{1,76} By 4 to 7 months of age, infants metabolize and eliminate caffeine in a manner similar to adults.¹⁰ All patients demethylate some quantity of caffeine to active metabolites, including theophylline and theobromine. The degree to which this occurs depends on the patient's age, CYP1A2 induction status, and other factors.

Less than 5% of caffeine is excreted in the urine unchanged. The half-life of caffeine is highly variable and dependent on several factors. Generally speaking, younger patients, particularly infants as well as patients with CYP1A2 inhibition, such as pregnant patients and patients with cirrhosis, have longer caffeine half-lives than the 4.5-hour half-life in healthy, adult, nonsmoking patients.^{34,52,57,89}

Caffeine Toxicokinetics. Caffeine toxicity is a dose dependent phenomenon. The range of toxic concentrations reported in different references varies greatly, and no definite conclusions can be drawn regarding the relationship between serum concentrations and symptomatology in overdose. Therapeutic dosing in neonates is typically a loading dose of 20 mg/kg, with daily maintenance dosing of 5 mg/kg. Based on case reports and series, lethal dosing in adults is estimated at 150 to 200 mg/kg, and death may occur with serum concentrations above 80 $\mu\text{g/mL}$. Numerous fatalities are reported with serum concentrations under 200 $\mu\text{g/mL}$; and survival is reported of a patient with an acute caffeine overdose and a serum concentration over 400 $\mu\text{g/mL}$.¹⁹⁴ Infants tolerate greater serum concentrations of caffeine than do children and adults.

Theophylline Pharmacokinetics

Theophylline is approximately 100% bioavailable by the PO and IV routes. Many of the available PO preparations are sustained release designed to provide stable serum concentrations over a prolonged period of time with less frequent dosing. Peak absorption for immediate-release preparations is 60 to 90 minutes; peak absorption of sustained-release preparations generally occurs 6 to 10 hours after ingestion.

Similar to caffeine, theophylline rapidly diffuses into the total body water and all tissues, readily crosses the blood–brain barrier, and crosses into the placenta and breast milk.¹⁴ The Vd of theophylline is 0.5 L/kg, and 56% of it is protein bound at therapeutic concentrations.

Theophylline is metabolized primarily by CYP1A2. The major pathway is demethylation to 3-methylxanthine in addition to being demethylated or oxidized to other metabolites. Less than 10% of theophylline is excreted in the urine unchanged.

Similar to caffeine, the half-life of theophylline is highly variable and depends on several factors. In healthy, adult, nonsmoking patients, the half-life is 4.5 hours. Infants and elderly adults as well as patients with CYP1A2 inhibition, pregnant patients, and those with cirrhosis may have theophylline half-lives twice as long as healthy children and nonsmoking adults.^{100,132,188} Factors that induce CYP1A2, such as cigarette smoking, or others that inhibit CYP1A2, such as

exposure to cimetidine, macrolides, and oral contraceptives, can significantly alter theophylline clearance.^{84,130,146,147,162,199} Cessation of smoking, such as when a patient with chronic obstructive pulmonary disease develops bronchitis, leads to a reversal of CYP1A2 induction and predisposes to the development of chronic toxicity.

Theophylline Toxicokinetics. As in the case of caffeine, theophylline exhibits Michaelis-Menten kinetics, presumably when greater than a single therapeutic dose is taken.¹⁵² At higher doses and in overdose, it undergoes zero-order elimination, and only a fixed amount of the drug can be eliminated in a given time because of saturation of metabolic enzymes.¹⁵⁹

Therapeutic serum concentrations of theophylline are 5 to 15 µg/mL. Although morbidity and mortality are not always predictable based on serum concentrations, life-threatening toxicity is associated with serum concentrations of 80 to 100 µg/mL in acute overdoses and of 40 to 60 µg/mL in chronic overdoses.

Theobromine Toxicokinetics and Pharmacokinetics

Similar to the other methylxanthines, theobromine is well absorbed from the gastrointestinal (GI) tract and is 80% bioavailable when administered in solution. It is completely bioavailable orally and rectally. Theobromine has 21% protein binding, a Vd of 0.62 L/kg, and a serum half-life of 6 to 10 hours.^{62,156} Theobromine undergoes hepatic metabolism by CYP1A2 and CYP2E1.³¹ Theobromine is excreted in breast milk. Toxic concentrations of theobromine in animals are known, but comparable human data are lacking.

Selective β_2 -Adrenergic Agonist Pharmacokinetics

The β_2 -adrenergic agonists are bioavailable by both inhalation and ingestion, and much of “inhaled” β_2 -adrenergic agonists may actually be swallowed and absorbed from the GI tract. Absorption, distribution, and elimination are quite variable. The half-life of albuterol is approximately 4 hours, less than 5% crosses the blood–brain barrier, it is metabolized extensively in the liver, and it is excreted in urine and feces as albuterol and metabolites.³

Terbutaline is partially metabolized in the liver, mainly to inactive conjugates. With parenteral administration, 60% of a given dose is excreted in the urine unchanged.²

Clenbuterol has a terminal half-life of approximately 22 hours and a prolonged duration of action. It is more potent than other β_2 -adrenergic agonist, with a typical therapeutic dose of 20 to 40 µg, as opposed to milligram doses for other β_2 -adrenergic agonists.

Selective β_2 -Adrenergic Agonist Toxicokinetics. Overdose of albuterol, which happens predominantly in young children treated with oral albuterol preparations, may cause significant effects.¹¹⁵ For oral albuterol poisoning 1 mg/kg appears to be the dose threshold for developing clinically significant toxicity.²⁰⁵

Clenbuterol toxicity occurs following illicit drug use by ingestion, intranasal, and IV use of clenbuterol or clenbuterol-tainted street drugs.⁹⁶

Methylxanthine and β_2 -Adrenergic Agonist Toxicity

Caffeine, theobromine, and theophylline affect the same organ systems and cause qualitatively similar effects. There are distinct differences in the activity and effects of the various methylxanthines, particularly in therapeutic dose. Toxicity affects the GI, cardiovascular, central nervous, and musculoskeletal systems in addition to causing a constellation of metabolic derangements. A putative cause for toxicity involves the increase in metabolism that occurs with methylxanthine toxicity, particularly in the setting of a decreased tissue perfusion.

Concomitant poisoning with other xenobiotics that result in adrenergic stimulation, such as pseudoephedrine, ephedrine, amphetamines, or cocaine, may be particularly severe.^{58,203}

Gastrointestinal. In overdose, methylxanthines cause nausea, and most significant acute overdoses result in severe and protracted emesis. Whereas emesis occurs in 75% of cases of acute theophylline poisoning, only 30% of cases of chronically poisoned patients have emesis.¹⁸¹ When it occurs, the emesis may be difficult to control despite the use of potent antiemetics. This is especially evident with sustained-release theophylline preparations.⁴ Emesis is less common with β_2 -adrenergic agonists, than with methylxanthine overdose.

Methylxanthines cause an increase in gastric acid secretion and smooth muscle relaxation. These factors contribute to the gastritis and esophagitis reported in chronic methylxanthine users.⁴⁶ Gastritis is noted in drinkers of decaffeinated coffee, indicating that some adverse gastric effects associated with coffee drinking may be caused by ingredients other than caffeine or even the pH of the beverage.

Cardiovascular. Methylxanthines are cardiac stimulants and result in positive inotropy and chronotropy even with therapeutic dosing. Dysrhythmias, particularly tachydysrhythmias, are common in patients with methylxanthine overdose.

Tachydysrhythmias, particularly ventricular extrasystoles, are more common after overdose of methylxanthines.^{42,139,174} Cardiac dysrhythmias, although described with β_2 -adrenergic agonist poisoning, are most frequently supraventricular in origin and clinically inconsequential. Dysrhythmias other than sinus tachycardia associated with β_2 -adrenergic agonist toxicity are not routinely noted with toxicity from other β_2 -adrenergic agonists, but clenbuterol may result in atrial fibrillation.⁵⁵ Palpitations, tachycardia, and chest pain are common presenting complaints for patients with clenbuterol toxicity.

In the setting of acute poisoning, generally benign sinus tachycardia is nearly universal in patients without antecedent cardiac disease. In any patient, particularly those with underlying cardiac disease, sinus tachycardia may degenerate to a more severe rhythm disturbance, and these represent the most common causes of fatality associated with methylxanthine poisoning. Both atrial and ventricular dysrhythmias, including supraventricular tachycardia (SVT), multifocal atrial tachycardia, atrial fibrillation, premature ventricular contractions, and ventricular tachycardia, may all result from methylxanthine toxicity.^{21,178} Electrolyte disturbances, particularly hypokalemia, may be a contributing factor in the development of dysrhythmias. Dysrhythmias occur more commonly and at lower serum concentrations in cases of chronic poisoning with methylxanthines. Consequential dysrhythmias occur in 35% of patients with chronic theophylline poisoning but in only 10% of acute poisoning.¹⁷⁸ Ventricular dysrhythmias occur at serum concentrations of 40 to 80 $\mu\text{g/mL}$ in patients with chronic theophylline overdoses and most commonly at serum concentrations greater than 80 $\mu\text{g/mL}$ in patients with acute overdoses. Neonates born to mothers who consumed more than 500 mg/day of caffeine are more likely to have dysrhythmias compared with cohorts born to mothers consuming less than 250 mg/day of caffeine.⁸⁶ See [Table 66–1](#) for the caffeine content of other popular products.

Myocardial ischemia and myocardial infarction (MI) may result from acute caffeine or theophylline poisoning.^{69,91,134} MI is associated with albuterol⁶⁶ and more recently clenbuterol.¹¹⁴ Isoproterenol, once a common asthma therapy before widespread use of selective β_2 -adrenergic agonists, has both β_1 - and β_2 -adrenergic agonist activity and is a well-reported cause of MI. Given the frequency of use of selective β_2 -adrenergic agonists as well as toxicity and adverse effects reported from them, MI should be considered unlikely to occur. The same cannot be presumed about clenbuterol because the toxicity profile for this drug is still emerging. Clenbuterol is clearly documented to cause myocardial ischemia and MI in young otherwise healthy patients without coronary artery disease.¹¹⁴

Elevation of troponin, muscle creatine phosphokinase (CK-MM) and cardiac (CK-MB) fractions after large doses of β_2 -adrenergic agonist, particularly terbutaline infusions and continuous albuterol nebulization, is described.^{49,50,109,193} In the absence of electrocardiographic (ECG) changes suggestive of ischemia, the clinical significance of increased CPK-MB and cardiac troponins in patients receiving terbutaline infusions, particularly children, is unclear and has not been demonstrated to correlate with clinically adverse effects.⁴⁴

In therapeutic doses, methylxanthines cause cerebral vasoconstriction, which is a desirable effect when caffeine is used to treat a migraine headache. However, in overdose, this effect likely exacerbates CNS toxicity by diminishing cerebral perfusion.¹³⁴ Tolerance to the vasopressor effects of methylxanthines develops after several days of use and rapidly disappears after relatively brief periods of abstinence.

Dietary caffeine use is associated with a significant increase in blood pressure that may contribute to population levels of morbidity and mortality.¹⁰³ At elevated serum concentrations, patients with methylxanthine or β_2 -adrenergic agonist poisoning often develop a characteristic widened pulse pressure. This is caused by enhanced inotropy (β_1) and may result in increases in systolic blood pressure combined with peripheral vasodilation (β_2), which may result in diastolic hypotension. In cases of acute theophylline overdose, serum concentrations greater than 100 $\mu\text{g/mL}$ are usually associated with significant hypotension.

Methylxanthines cause renal vasodilation that, in addition to the increased cardiac output, results in a mild diuresis.¹⁴⁸

Pulmonary. Methylxanthines stimulate the CNS respiratory center, causing an increase in respiratory rate. For this reason, caffeine and theophylline are used to treat neonatal apnea syndromes. Caffeine and theophylline overdose may cause hyperventilation, respiratory alkalosis, respiratory failure, respiratory arrest, and acute respiratory distress syndrome.

Neuropsychiatric. The stimulant and psychoactive properties of methylxanthines, particularly caffeine, elevate mood and improve performance of manual tasks.^{26,36,102} These stimulant effects are some of the reasons caffeine is so widely used. CNS stimulation is an effect sought by users of coffee, tea, cocoa, and chocolate, but CNS stimulation resulting from therapeutic use of theophylline is generally considered to be an undesirable side effect. Although at low doses methylxanthines have beneficial effects, with increasing doses, they result in adverse effects. Headache, anxiety, agitation, insomnia, tremor, irritability, hallucinations, and seizures may result from caffeine or theophylline poisoning. In adults, caffeine doses of 50 to 200 mg result in increased alertness, decreased drowsiness, and lessened fatigue, and caffeine doses of 200 to 500 mg produce adverse effects such as tremor, anxiety, diaphoresis, and palpitations. Children tend to develop CNS symptoms at lower serum theophylline concentrations than adults, and such excitation is a significant clinical

disadvantage of theophylline use.

Seizures are a major complication of methylxanthine poisoning. The ability of caffeine to both promote and prolong seizures is well recognized. Caffeine has been used to prolong therapeutically induced seizures in electroconvulsive therapy.^{54,112} Seizures resulting from methylxanthine overdose tend to be severe and recurrent and may be refractory to conventional treatment. Antagonism of adenosine, the endogenous neurotransmitter responsible for halting seizures, contributes to the profound seizures associated with methylxanthine overdose.^{64,70,179,209} When studied prospectively, chronic theophylline toxicity results in seizures in 14% of patients, but 5% of acutely poisoned patients experience seizures. In cases of chronic and acute-on-chronic toxicity, seizures are more likely to occur, and they occur at lower serum concentrations.¹⁵⁰ Patients at extremes of age—those younger than age 3 years and older than age 60 years—are more likely to experience seizures with overdose.

Musculoskeletal. Methylxanthines increase striated muscle contractility, secondarily decreasing muscle fatigue. They also increase muscle oxygen consumption and increase the basal metabolic rate. These effects are sought by users to enhance or improve athletic performance or weight loss.^{9,19,46,65,79,80} All methylxanthines cause smooth muscle relaxation.

Tremor is the most common adverse effect of methylxanthines. Skeletal muscle excitation, which may include fasciculation, hypertonicity, myoclonus, or even rhabdomyolysis, may occur with methylxanthine overdose.^{119,129,164,208} Mechanisms by which rhabdomyolysis may result include increased muscle activity, particularly from seizures, and direct cytotoxicity from excessive sequestered intracytoplasmic calcium. Interestingly, multiple case reports associate atraumatic compartment syndrome with rhabdomyolysis with theophylline overdose.^{128,195}

Metabolic. Numerous metabolic derangements result from acute methylxanthine toxicity and are similar to those in other hyperadrenergic situations.^{84,88,168,180}

Severe hypokalemia may result from β_2 -adrenergic stimulation.¹⁹⁶ This results from influx of extracellular potassium into the intracellular compartment despite normal total body potassium content. Both ECG and neuromuscular complications of hypokalemia may develop. Other metabolic effects of methylxanthine and β_2 -adrenergic agonist poisoning include hypomagnesemia and hypophosphatemia.^{30,115,202}

Transient hypokalemia resulting from β -adrenergic agonism occurs in 85% of patients with acute theophylline overdose, and typically the serum potassium decreases to approximately 3 mEq/L.^{5,183} Stimulation of Na^+K^+ -ATPase results in a shift of serum potassium to the intracellular compartment of skeletal muscle. Total body potassium stores are unchanged. The significance of hypokalemia in patients with methylxanthine overdose is unclear. Vomiting and renal losses do not contribute significantly to hypokalemia, but these may result in fluid loss. Hyperkalemia may result from rhabdomyolysis and overly aggressive repletion of potassium.

Metabolic acidosis with increased serum lactate concentration is commonly noted as a complication of theophylline overdose.^{25,124} Tachypnea and respiratory alkalosis secondary to stimulation of the respiratory center are also common. Clenbuterol excess demonstrates significant β_2 -adrenergic agonists toxicity associated with an anion gap metabolic acidosis in some cases.⁹⁶

Hyperglycemia with serum glucose of approximately 200 mg/dL in those without diabetes is common and occurs in 75% of patients with acute theophylline overdose. Hyperthermia caused by increased metabolic activity and increased muscle activity may result from caffeine and theophylline overdose. Leukocytosis, probably secondary to the high concentrations of circulating catecholamines, results from acute methylxanthine overdose. This phenomenon apparently lacks clinical significance. In the absence of seizures or protracted emesis, chronic methylxanthine poisoning does not typically lead to metabolic derangements because such toxicity is an ongoing, compensated process.

Chronic Methylxanthine Toxicity

The distinction between acute and chronic toxicity is based on the duration of exposure to the xenobiotic. Patients with chronic toxicity may manifest subtle signs such as anorexia, nausea, palpitations, or emesis, although they may also present with seizures or dysrhythmias.

Patients chronically receiving theophylline or caffeine have higher total body stores and often underlying medical disorders, and they may develop toxicity with a smaller amount of additional theophylline or caffeine. Chronic methylxanthine poisoning typically occurs in the setting of therapeutic use of theophylline and may occur with iatrogenic administration of caffeine or from frequent, chronic consumption of caffeinated products. Patients often manifest subtle signs of illness, such as anorexia, nausea, palpitations, or emesis. However, the initial presentation in these patients, even with serum concentrations in the 40 to 60 $\mu\text{g/mL}$ range, may be a seizure. In children chronically overdosed with theophylline, the peak serum theophylline concentration may fail to identify those who will progress to life-threatening toxicity. In the absence of protracted emesis or seizures, the initial electrolytes and blood gases are expected to be normal in patients with chronic methylxanthine toxicity.

Chronic Methylxanthine Use

Data on the effect of caffeine on many chronic health issues are mixed and highly contradictory. Studies show inconclusive links to cancer, heart disease, osteoporosis, hyperlipidemia, and hypercholesterolemia associated with caffeine use.^{68,71,83,160,206} Excessive consumption of caffeine-containing beverages may cause hypokalemia.¹⁶³

Caffeine Withdrawal

Caffeine induces tolerance, and a withdrawal syndrome, including headache, yawning, nausea, drowsiness, rhinorrhea, lethargy, irritability, nervousness, a disinclination to work, and depression, may result upon abstinence.¹⁹² Caffeine withdrawal symptoms are described in neonates born to mothers with consequential caffeine use.¹³⁶ The onset of caffeine withdrawal symptoms begins 12 to 24 hours after cessation and lasts up to one week.⁸² In a double-blind trial, 52% of adults with low to moderate caffeine intake, defined as 2.5 cups of coffee daily, developed a withdrawal syndrome upon caffeine abstinence.¹⁸⁶

Reproduction

Massive doses of methylxanthines are teratogenic, but the doses of typical use are not associated with birth defects. Decreased fecundity and adverse fetal outcome are noted in animals with chronic exposure to methylxanthines.^{72,77,135} Human studies of fertility, fetal loss, and fetal outcome produce divergent results, and the effects of methylxanthines use during gestation are unclear.^{99,106,141,144}

Diagnostic Testing

An ECG, serum electrolytes, and serum caffeine or theophylline concentrations are indicated as appropriate in cases of suspected methylxanthine toxicity. Because toxicity is dose related in acute overdose, serum concentrations of caffeine and theophylline may be loosely applied as a correlate with toxicity.

Hospitals in which caffeine is used therapeutically typically have the capability to assay serum caffeine concentration within the institution, and likewise hospitals in which theophylline is used therapeutically typically are able to assay serum theophylline concentrations. Overdose of caffeine may result in a spuriously elevated serum theophylline concentration.^{67,107}

Theophylline concentrations, and to a lesser extent, caffeine concentrations, may be used prognostically to guide management of poisoning. Proper interpretation requires knowledge of whether the poisoning is acute, chronic, or acute on chronic. In the setting of toxicity, serum methylxanthine concentrations should be obtained immediately and then serially every 1 to 2 hours until a downward trend is evident.

Likewise, serum electrolytes, particularly potassium, should be monitored serially as long as the poisoned patient remains symptomatic and such values are in a range that may warrant treatment. Cardiac monitoring should continue until the patient is free of dysrhythmias other than sinus tachycardia, has a falling serum methylxanthine concentration, and is clinically stable. In patients with systemic illness, hyperthermia, or increased muscle tone, assessing serum CK and urinalysis to detect rhabdomyolysis is also indicated.

MANAGEMENT

General Principles and Gastrointestinal Decontamination

After assuring adequacy of airway, breathing, and circulation, supportive care and maintenance of vital signs within acceptable limits are the mainstays of therapy for patients with methylxanthine and selective β_2 -adrenergic agonist toxicity. Decisions regarding GI decontamination, including orogastric lavage, administration of activated charcoal (AC), or whole-bowel irrigation (WBI), depend on the dosage and type of preparation involved, the time since exposure, and the patient's physical condition ([Chap. 8](#)). AC is the only GI decontamination that should be routinely considered for selective β_2 -adrenergic agonist ingestion.

Emesis. Induced emesis is not indicated for selective β_2 -adrenergic agonist ingestion or methylxanthine ingestion. A simulated overdose controlled volunteer study with sustained-release theophylline was unable to demonstrate reduction of absorption of theophylline in patients treated with syrup of ipecac.¹⁴² Seizures are possible with any significant methylxanthine poisoning, and induced emesis in a patient with potential to experience a seizure is contraindicated. Because the benefits of emetics are undemonstrated and emesis interferes with administration of AC, induced emesis is rarely considered for those with methylxanthine poisoning.^{6,175}

Orogastric Lavage. Orogastric lavage may be considered for patients with potentially toxic methylxanthine ingestions who reach medical care shortly after ingestion. Selective β_2 -adrenergic agonist liquid ingestion that occurs within one hour

before treatment may warrant aspiration through a small nasogastric tube.

Ingestion of sustained-release theophylline tablets is associated with the formation of bezoars that may be difficult to remove or dislodge. Treatment in such cases has included endoscopic removal.⁴⁰

Activated Charcoal. AC is essential in the treatment of methylxanthine poisoning. AC can adsorb methylxanthines and selective β_2 -adrenergic agonist present in the GI tract and limit their absorption. Multiple-dose activated charcoal (MDAC) is helpful to enhance the elimination of methylxanthine toxicity but is not indicated for selective β_2 -adrenergic agonist ingestion. MDAC may be useful for any sustained-release methylxanthine preparation. Additionally, MDAC enhances elimination of theophylline by “gut dialysis” (Antidotes in Depth: A1). Such enhanced elimination by gut dialysis is not demonstrated experimentally or otherwise for caffeine or theobromine toxicity. Because caffeine is to some extent metabolized to theophylline, in cases of caffeine poisoning, MDAC would at the very least enhance elimination of theophylline metabolites. The pharmacologic similarity of the methylxanthines and the relative safety of MDAC therapy warrant the use of such treatment for patients with any methylxanthine toxicity. MDAC is used for enhanced elimination.

Whole-Bowel Irrigation. Treatment of patients with significant ingestions of sustained-release pills may include WBI with a balanced electrolyte solution to enhance GI elimination (Antidotes in Depth: A2). Polyethylene glycol electrolyte lavage solution used for WBI may displace theophylline already bound to activated charcoal.⁹⁵ This may be a particular problem in patients who have taken several doses of AC before WBI, in which desorption of methylxanthines from AC may result in a bolus of methylxanthines available for GI absorption. Also, WBI is experimentally demonstrated to provide no additional benefit to AC in treatment of sustained-released theophylline ingestion.³⁸ Despite these data, WBI with MDAC remains the preferred and recommended treatment of a patient with ingestion of sustained-release theophylline.

Selecting a Method of Decontamination. The use of decontamination methods that involve more than minimal risk, specifically orogastric lavage, should only occur after careful consideration of the indications. Patients with potentially life-threatening acute ingestions occurring approximately one hour previously may be treated with orogastric lavage (Chap. 8).

Treatment

Gastrointestinal Toxicity. Phenothiazine antiemetics are contraindicated in those with methylxanthine poisoning because they are typically ineffective and may lower the seizure threshold. The preferred antiemetic is ondansetron, although metoclopramide may be used also.^{53,157,167} Ondansetron dosing in the upper end of the therapeutic dosing range, or even chemotherapeutic doses may be used if necessary. Histamine (H_2) blockers or proton pump inhibitors may be administered to any patient with hematemesis. Cimetidine is contraindicated because it inhibits multiple CYP enzymes, delaying clearance of methylxanthines.

Cardiovascular Toxicity. Patients with hypotension should initially be treated by administration of isotonic IV fluid, such as 0.9% sodium chloride or lactated Ringer solution, in bolus volumes of 20 mL/kg. If acceptable blood pressure cannot be maintained despite several fluid boluses or if there are contraindications to fluid bolus, vasopressor therapy should be considered.

Methylxanthine and selective β_2 -adrenergic agonist toxicity may cause hypotension via β -adrenergic agonism; therefore, administration of vasopressors with β -adrenergic agonist effects, such as epinephrine, dobutamine, or isoproterenol, is suboptimal. An α -adrenergic agonist such as phenylephrine is the first-line pressor of choice in such a situation, although norepinephrine is also acceptable (Table 66–2).

TABLE 66–2. Therapeutic Interventions for Methylxanthines and Selective β_2 -Adrenergic Agonist Poisoning

System	Indication	Therapeutic Agent	Comments
Cardiovascular	Hypotension	Vasopressors	Relatively contraindicated in asthmatic patients Requires hemodynamic monitoring Hypotension unresponsive to IV fluid
		Phenylephrine	
		Norepinephrine	
		β-Adrenergic antagonists	
	Supraventricular dysrhythmias	Esmolol	Relatively contraindicated in asthmatic patients Requires hemodynamic monitoring
		Metoprolol	
		Propranolol	
		Calcium channel blockers	
		Diltiazem	
		Verapamil	
	Ventricular dysrhythmias	β-Adrenergic antagonists	Relatively contraindicated in asthmatic patients Requires hemodynamic monitoring
		Esmolol	
		Metoprolol	
		Propranolol	
		Antidysrhythmics	
		Lidocaine	
		β-Adrenergic antagonists	
		Esmolol	
		Metoprolol	
		Propranolol	
Gastrointestinal	Emesis	Antiemetics	Cimetidine is not recommended as it may decrease clearance of methylxanthines and prolong toxicity
		Metoclopramide	
		Ondansetron	
	Hematemesis	Granisetron	
		Proton pump inhibitors	
		Esomeprazole or others	
		H ₂ antagonists	
Central nervous system	Agitation	Ranitidine	
		Famotidine	
	Anxiety	Benzodiazepines	
		Diazepam	
		Lorazepam	
	Seizures	Benzodiazepines	
		Diazepam	
		Lorazepam	
		Midazolam	
		Barbiturates	
		Phenobarbital	
		Pentobarbital	
		Propofol	
Metabolic	Metabolic acidosis	Sodium bicarbonate (controversial)	Not routinely recommended for this purpose
	Hypokalemia	Potassium chloride	Relatively contraindicated in asthmatic patients Requires hemodynamic monitoring
		β-Adrenergic antagonists	
		Esmolol	
		Metoprolol	
		Propranolol	

In rare cases of refractory hypotension, the administration of an adrenergic antagonist may be warranted.⁶⁰

Administration of an adrenergic antagonist to a hypotensive patient may seem counterintuitive, but it may reverse β_2 -adrenergic-mediated vasodilation. In addition, β_1 -adrenergic blockade treats tachycardia and any associated decreased cardiac output. In dogs with aminophylline-induced tachycardia and hypotension, administration of esmolol results in a return to normal heart rate and blood pressure, and it does not exacerbate hypotension.⁷³ Propranolol, esmolol, and metoprolol have been used successfully to treat methylxanthine-induced hypotension.^{27,154} It is most appropriate to use a β -adrenergic antagonist with a brief duration of action, such as esmolol, at least initially, in such circumstances. In the event of an adverse reaction or side effect such as hypotension or bronchospasm were to occur, the duration of such will be relatively brief. Any β -adrenergic antagonist therapy should ideally be preceded and accompanied by assessment of cardiac output and central venous pressure, either directly or noninvasively.¹¹³

Because of its long half-life and possibly potency, toxicity from clenbuterol exposure appears more likely to require treatment with β -adrenergic antagonist medications.⁹⁴

When drug toxicity is not in question, adenosine or electrical cardioversion are the preferred treatment for SVT, but this is not so for SVT resulting from methylxanthine toxicity. Because of the antagonist effects at the adenosine receptor, administration of adenosine should not be expected to convert a methylxanthine-induced SVT. However, even if adenosine is successfully used to convert an SVT, the effect is likely to be transient. Because methylxanthine toxicity has a global effect on the myocardium and methylxanthine concentrations do not change rapidly, cardioversion, which is effective in electrically “reorganizing” depolarization, is unlikely to result in a sustained normal rhythm.

The primary treatment for methylxanthine-induced SVT includes administration of benzodiazepines, which work to abate CNS stimulation and concomitant release of catecholamines. More focused pharmacologic therapy to treat SVT would be through cautious administration of a conduction-attenuating calcium channel blocker such as diltiazem or verapamil.

In animal models, treatment of acute theophylline toxicity with the calcium channel blockers diltiazem, verapamil, and nifedipine each results in decreased cardiac-related deaths and prevention of dysrhythmias, hypotension, myocardial necrosis, and seizures.²⁰⁴ In addition to the cardiovascular benefit of calcium channel blockers, they may also afford neurologic protection and prevention of seizure. In patients without asthma, methylxanthine-induced SVT and other tachydysrhythmias may be treated by administration of an adrenergic antagonist.

Central Nervous System Toxicity. Administration of a benzodiazepine, such as diazepam, lorazepam, or midazolam, is appropriate treatment for anxiety, agitation, or seizure. Seizures associated with methylxanthine toxicity are severe and often refractory to treatment. Seizures not controlled with one or two therapeutic doses of a benzodiazepine should be treated with a barbiturate such as phenobarbital or pentobarbital or another suitable sedative-hypnotic such as propofol. No delay should occur before administering such medications. Unsuccessful treatment of methylxanthine-induced seizures with any particular antiepileptic should quickly be abandoned in favor of treatment with an additional or more potent and efficacious anticonvulsant. The administration of barbiturates may result in or exacerbate hypotension. Treatment of agitation or seizure with benzodiazepines, barbiturates, or other sedative-hypnotic may require repeated dosing until clinical effect is achieved.

Administration of phenobarbital to prevent seizures in theophylline-poisoned rabbits and mice increases survival by decreasing the incidence of seizures.^{51,78} Although historically, phenobarbital was the recommended drug for such prophylaxis, use of a benzodiazepine such as lorazepam seems preferable based on pharmacokinetic and practical considerations. Patients at risk for seizure include those identified earlier in this chapter—patients older than age 60 years or younger than age 3 years, those with chronic overdose and a serum concentration above 40 $\mu\text{g/mL}$, and acutely overdosed patients with serum concentrations greater than 100 $\mu\text{g/mL}$.

Phenytoin and fosphenytoin are of no benefit in controlling methylxanthine-induced seizures, and they have no role in such treatment.^{93,133} Retrospective review of human cases demonstrated phenytoin to be ineffective in treating seizures in 21 of 22 cases.¹⁰¹ Phenytoin results in the occurrence of seizures at an earlier time after overdose and results in higher mortality when administered to theophylline-poisoned mice.²⁸

Metabolic Derangements. Patients with symptomatic hypocalcemia should be treated with electrolyte repletion. Most cases of mild hypokalemia are well tolerated, but any patient with symptomatic hypokalemia, particularly those associated with ECG changes of T waves or QT interval prolongation, should be treated. The frequency of ventricular dysrhythmias in methylxanthine poisoning is exacerbated by hypokalemia coupled with increased intrinsic catecholamine release. Correction of hypokalemia may be crucial in methylxanthine poisoning associated with ventricular dysrhythmias.

There is no specific degree of hypokalemia that absolutely necessitates treatment. In the absence of associated dysrhythmia, the clinical significance of such hypokalemia is unclear. Although correction is generally performed with the administration of IV or PO potassium, hypokalemia experimentally responds to treatment with β -adrenergic antagonists.

Cautious administration of potassium to treat symptomatic hypokalemia may be indicated, but this is distinct from higher doses of potassium used in total body potassium repletion. In cases of hypokalemia secondary to β -adrenergic agonism, after the β -adrenergic agonism returns to baseline level, an efflux of potassium from the intracellular compartment occurs. A concomitant increase in the serum potassium concentration occurs at that time. Overly aggressive attempts to correct

hypokalemia may result in hyperkalemia after the β -adrenergic agonist effects abate. Acute methylxanthine-induced hypokalemia may be treated with potassium supplementation, but because of the nature of the problem with excess β -adrenergic agonism, potassium supplementation is typically unnecessary and poorly effective.

Experimentally, administration of propranolol to theophylline-poisoned dogs prevented or partially reversed hypokalemia, hypophosphatemia, hyperglycemia, and metabolic acidosis as well as hypotension.¹¹¹ Prevention or correction of the metabolic derangements associated with theophylline toxicity by administration of β -adrenergic antagonists is congruent with the fact that these derangements, particularly hypokalemia, are the consequence of β -adrenergic agonism. The efficacy of β -adrenergic antagonists as therapy for hypokalemia resulting from acute methylxanthine poisoning in humans is unstudied.

Hypomagnesemia, hypophosphatemia, and hypocalcemia should be treated as they would for other patients. As with hypokalemia, QT interval prolongation is an absolute indication to treat these derangements.

Hyperglycemia, likely resulting from increased circulating catecholamines, is common. This hyperglycemia does not necessitate treatment, both because it is a transient effect and because in other situations of hyperglycemia resulting from adrenergic agonism, rebound hypoglycemia may occur.

Musculoskeletal Toxicity. The use of benzodiazepines is appropriate treatment for fasciculations, hypertonicity, myoclonus, and rhabdomyolysis. Rhabdomyolysis necessitates aggressive IV fluid therapy, possibly with sodium bicarbonate (Antidotes in Depth: A5).

Enhanced Elimination. Fortunately, methylxanthine toxicity lends itself well to several methods of enhanced elimination, including GI dialysis with MDAC, charcoal hemoperfusion, and hemodialysis, as well as lesser used methods such as continuous arteriovenous hemoperfusion, continuous venovenous hemoperfusion, and plasmapheresis.^{16,120,126}

Infants with methylxanthine poisoning may be too ill, unstable, or small to be treated with hemodialysis or hemoperfusion. Both MDAC and exchange blood transfusion are effective methods of enhanced elimination in infants and may be the preferred method of treatment in these patients if hemodialysis is unavailable.^{151,153,182,184}

The therapeutic effects of AC in such cases are much greater than simply limiting absorption of ingested methylxanthines. AC, particularly MDAC, allows elimination of theophylline through GI dialysis.¹³ MDAC is extremely effective at enhancing elimination of theophylline.^{24,74,125,149} Experimentally in dogs, rabbits, and human volunteers, AC administered after IV aminophylline administration results in increased systemic clearance and decreased half-life of theophylline.^{98,117,137,155} The pharmacologic similarity of the methylxanthines suggests that MDAC may be effective in caffeine or theobromine poisoning, and MDAC certainly is effective in eliminating theophylline generated from metabolism of caffeine or theobromine. The efficacy of MDAC combined with the safety and ease with which this therapy can be administered makes MDAC the mainstay of enhanced elimination in methylxanthine toxicity. Severe emesis associated with methylxanthine poisoning may result in intolerance of MDAC¹⁷⁶ (Antidotes in Depth: A1).

Charcoal hemoperfusion was once considered the most effective method of enhanced elimination of methylxanthines, decreasing theophylline's half-life to 2 hours and increasing its clearance up to sixfold.^{37,144,165,207} Variations of charcoal hemoperfusion, including albumin colloid hemoperfusion, resin hemoperfusion, and charcoal hemoperfusion in series with hemodialysis, are reported.^{41,97,121,158,191} If hemoperfusion is available, it is preferable, but when charcoal hemoperfusion is unavailable,¹⁷⁷ hemodialysis is excellent and has become routine therapy.

Hemodialysis is slightly less efficient than hemoperfusion in the extracorporeal removal of methylxanthines.^{8,122,124,187} The ability of hemodialysis to correct fluid and electrolyte imbalances, the greater availability of hemodialysis in many regions, greater technical ease, and lower complication rates have resulted in a paradigm shift from considering charcoal hemoperfusion to be the definitive treatment for significant methylxanthine toxicity to one in which charcoal hemoperfusion and hemodialysis are considered equivalent treatment options.¹⁸⁵

The specific indications for hemodialysis are not agreed upon. In the treatment of patients with methylxanthine poisoning. Several studies and clinical experience are the basis for the following suggested indications for extracorporeal elimination by charcoal hemoperfusion, hemodialysis, combined charcoal hemoperfusion and hemodialysis, or combined hemodialysis and MDAC.

Many recommendations regarding hemoperfusion and hemodialysis for theophylline toxicity use serum theophylline concentration as a guideline. Serum concentrations may not be available in instances of caffeine poisoning and do not exist for theobromine poisoning. Thus, the clinical aspects of theophylline management guidelines can be generalized to all methylxanthine toxicities.

When indicated, hemodialysis preferably should be initiated while the patient is still hemodynamically stable. Hemodialysis therapy should be used for patients with clinically significant chronic theophylline poisoning associated with a serum theophylline concentration above 40 to 60 $\mu\text{g/mL}$ or with a deteriorating clinical status.

Hemodialysis should be strongly considered any time a methylxanthine exposure results in a serum theophylline or caffeine concentration of greater than 90 $\mu\text{g/mL}$ and symptoms regardless of clinical stability (Table 66–3). Any patient with a symptomatic methylxanthine poisoning that is associated with ventricular dysrhythmias, seizures, hypotension

unresponsive to fluids, or emesis unresponsive to antiemetics should also be treated with charcoal hemoperfusion, hemodialysis, or both.

TABLE 66-3. Methylxanthine Poisoning: Indications for Charcoal Hemoperfusion or Hemodialysis

1. Acute serum theophylline or caffeine concentration $>90\text{ }\mu\text{g/mL}$ and any symptom
2. Serum theophylline or caffeine concentration $>40\text{ }\mu\text{g/mL}$ and
 - A. Seizures
 - B. Hypotension unresponsive to intravenous fluid or
 - C. Ventricular dysrhythmias

The fact that a patient experiences seizure or dysrhythmias or becomes extremely ill is not a contraindication for extracorporeal drug removal. To the contrary, these events make administration of such therapy more critical to ensure survival of the patient.

Treatment of Chronic Methylxanthine Toxicity

Treatment of chronic methylxanthine toxicity is determined by the patient's clinical status and by the efficacy of MDAC. The precise serum theophylline or caffeine concentration at which patients with chronic theophylline or caffeine toxicity should receive hemodialysis is controversial. For a hemodynamically stable patient without signs of life-threatening methylxanthine toxicity such as ventricular dysrhythmias or seizures, therapy with MDAC may be sufficient. If the serum theophylline or caffeine concentration does not decline after the administration of AC or if the patient's clinical status deteriorates, hemodialysis is indicated.

Treatment of Acute-on-Chronic Methylxanthine Toxicity

Patients chronically receiving theophylline or caffeine who acutely overdose should be initially managed in the same manner as patients with acute overdose, although action concentrations for dialysis are the same for chronic toxicity. Total body stores of the methylxanthines are higher in patients who are chronically exposed, and the threshold for toxicity may be reached at lower serum concentrations.

SUMMARY

- Caffeine is the most widely used methylxanthine, and as a result of novel products such as energy drinks and caffeinated alcoholic beverages, there are increasing numbers of poisoning from these products.
- Methylxanthine toxicity results from both the use of medicinals and therapeutics as well as foods and beverages.
- There are significant differences in the clinical presentation and management of patients with acute and chronic methylxanthine poisoning. Supportive care and treatment of GI, cardiovascular, CNS, metabolic, and musculoskeletal effects are the mainstay of therapy. The unique properties of methylxanthines necessitate specific therapies for the GI, cardiovascular, and CNS toxicities of methylxanthines.
- Methods of enhanced elimination, particularly extracorporeal elimination by charcoal hemoperfusion, hemodialysis, or combined charcoal hemoperfusion and hemodialysis in series, as well as gut dialysis with MDAC, are effective treatments for patients with methylxanthine toxicity.
- Selective β_2 -adrenergic agonists are widely used for the treatment of bronchospasm. Selective β_2 -adrenergic agonist toxicity typically results from excessive therapeutic use of these agents, but illicit use of clenbuterol or the admixture of clenbuterol with drugs of abuse has increased.

F. ANESTHETICS AND RELATED MEDICATIONS

67 LOCAL ANESTHETICS

David R. Schwartz and Brian Kaufman

HISTORY AND EPIDEMIOLOGY

Local anesthetics are xenobiotics that block excitation of and transmission along a nerve axon in a predictable and reversible manner. The anesthesia produced is selective to the chosen body part in contrast to the nonselective effects of a general anesthetic. Local anesthetics do not require the circulation as an intermediate carrier, and they usually are not transported to distant organs. Therefore, the actions of local anesthetics are largely confined to the structures with which they come into direct contact. Local anesthetics may provide analgesia in various parts of the body by topical application, injection in the vicinity of peripheral nerve endings and major nerve trunks, or via instillation within the epidural or subarachnoid spaces. The various local anesthetics differ with regard to their potency, duration of action, and degree of effects on sensory and motor fibers. Toxicity may be local or systemic. With systemic toxicity, the central nervous system (CNS) and cardiovascular systems typically are affected.

Until the 1880s, the only xenobiotics available for pain relief were centrally acting depressants such as alcohol and opioids, which blunted the perception of pain rather than attacking the root cause. The coca shrub (*Erythroxylon coca*) was brought back to Europe from Peru by Karl Von Scherzer, an Austrian explorer, in the mid-1800s. Some of the coca leaves were analyzed by the chemist Albert Niemann, who in 1860 successfully extracted and named the active principle, the alkaloid cocaine ([Chap. 78](#)). Sigmund Freud studied the use of cocaine to cure morphine addiction. Koller at the Ophthalmological Clinic at the University of Vienna dissolved coca powder in distilled water; instilled the solution in the conjunctival sacs of a frog, a rabbit, a dog, and himself; and noted that their corneas as well as his own could be touched without evidence of a reflex blink. In 1884, Koller performed an operation for glaucoma with only topical cocaine anesthesia; the news spread rapidly, leading to diversification of use.⁴³

Although the clinical benefits of cocaine anesthesia were significant, so were its toxic and addictive potential. At least 13 deaths were reported in the first 7 years after the introduction of cocaine in Europe, and within 10 years after the introduction of cocaine as a regional anesthetic, reviews of “cocaine poisoning” appeared in the literature.^{70,90} The toxicity of cocaine, coupled with the tremendous advantages it provided for surgery, led to a search for less toxic substitutes.

After the elucidation of the chemical structure of cocaine (the benzoic acid methyl ester of the alkaloid ecgonine) in 1895, other amino esters were examined. Synthetic compounds with local anesthetic activity were introduced, but they were highly toxic or irritating or had an impractically brief clinical effect. In 1904, Einhorn synthesized procaine, but its short duration of action limited its clinical utility. Research turned to focus on synthesis of xenobiotics with more prolonged durations of action.

The potent, long-acting local anesthetics dibucaine and tetracaine were synthesized in 1925 and 1928, respectively, and were introduced into clinical practice shortly thereafter. However, these anesthetics were not safe for regional anesthetic techniques because of potential systemic toxicity secondary to the combination of high potency, delayed metabolism, and the larger volumes of drug required for regional anesthesia compared with local anesthesia. On the other hand, these drugs were very useful for spinal anesthesia, which required much smaller volumes.

Lofgren synthesized lidocaine from a series of aniline derivatives in 1943. This amino amide combined high tissue penetrance and a moderate duration of action with acceptably low systemic toxicity. Additionally, the metabolites of lidocaine did not include para-aminobenzoic acid (PABA), which causes allergic reactions to all amino ester anesthetics. Subsequent to the release of lidocaine in 1944, several other amino amide compounds were introduced into clinical practice. These included mepivacaine in 1956, prilocaine in 1959, bupivacaine in 1963, etidocaine in 1971, and ropivacaine in 1996.

Considering how frequently local anesthetics are administered, both within and outside health care facilities, clinically significant toxic reactions are relatively uncommon, and most are iatrogenic. In reports of fatalities resulting from toxic exposures reported to US poison centers, local anesthetics are rarely implicated, representing less than 0.5% of cases ([Chap. 136](#)). Most poisonings result from inadvertent injection of a therapeutic dose into a blood vessel, repeated use of a therapeutic dose, or unintentional administration of a toxic dose. The amide local anesthetics have largely replaced the esters in clinical use because of their increased stability and relative absence of hypersensitivity reactions (see Pharmacology below). Poisoning from topical benzocaine is relatively common because of the large number of nonprescription products available for treatment of teething and hemorrhoids. In addition, there is widespread use of

benzocaine, mostly as a spray, for topical mucosal anesthesia before intubation, upper endoscopy, and transesophageal echocardiography. With nonprescription use, toxic effects after exposure are typically mild, and death rarely occurs. Toxicity usually occurs as a therapeutic misadventure, but child abuse or neglect should be considered if the patient is younger than 2 years, and suicide should be considered in older children and adults.

Benzocaine spray may be the most important cause of severe acquired methemoglobinemia in the hospital setting³ (Chap. 127). Between November 1997 and March 2002, the US Food and Drug Administration (FDA) received 198 reported adverse events secondary to benzocaine products. A total of 132 cases (66.7%) involved definite or probable methemoglobinemia; most were serious adverse events, and two deaths occurred.⁷⁹ In these cases, a single spray of unspecified duration of 20% benzocaine was the dose most commonly reported. Because of the difficulty in limiting the dose to the manufacturer's recommendation given the current formulations available, these authors recommend a metered dosing preparation and prominent package warnings.

PHARMACOLOGY

Local anesthetics fall into one of two chemically distinct groups: amino esters and amino amides (Fig. 67–1). The basic structure of all local anesthetics consists of three major components: a lipophilic, aromatic ring connected by an ester or amide linkage to a short alkyl, intermediate chain that is bound to a hydrophilic tertiary (or less commonly, secondary) amine. The amine is a base (proton acceptor) that is partially charged at physiologic pH.

FIGURE 67-1. Representative local anesthetics.

All local anesthetics function by reversibly binding to specific receptor proteins within the membrane bound sodium channels of conducting tissues. These receptors can be reached only via the cytoplasmic (intracellular) side of the cell membrane. Blockade of ion conductance through the sodium channel eventually leads to failure to initiate and propagate action potentials (Fig. 67-2). The analgesic effect results from inhibiting axonal transmission of the nerve impulse in small-diameter myelinated and unmyelinated nerve fibers carrying pain and temperature sensation. Conduction block of these fibers occurs at lower concentrations than in the larger fibers responsible for touch, motor function, and proprioception.²³ This likely occurs in myelinated nerves because smaller fibers have closer spacing of the nodes of Ranvier. Given that a fixed number of nodes must be blocked for conduction failure to occur, the shorter critical length of nerve is reached sooner by the locally placed anesthetic in small fibers.³⁷ For unmyelinated fibers, the smaller diameter limits the distance that such fibers can passively propagate the electrical impulse. In addition, differential nerve block may relate to voltage and time dependence of the affinity of local anesthetics to the sodium channels.

FIGURE 67–2. The multi-unit sodium channel is embedded in the nerve cell membrane. Local anesthetics (LA) enter the nerve cell at the exposed membranes of the nodes of Ranvier and bind to the cytoplasmic side of the sodium channel (also located at the node of Ranvier) and alter sodium conductance.

The sodium channel may exist in three states ([Chap. 24](#)). At resting membrane potential or in the hyperpolarized membrane, the channel is closed to sodium conductance. With an appropriate activating stimulus, the channel opens, allowing rapid sodium influx and membrane depolarization. Milliseconds later, the channel is inactivated, terminating the fast sodium current. Blockade is much stronger for channels that are activated (open) or inactivated than for channels that are resting. Pain fibers have a higher firing rate and longer action potential (ie, more time with the sodium channel open or inactivated) than other fiber types and therefore are more susceptible to local anesthetic action.⁵¹

These effects also occur in conductive tissues in the heart and brain that rely on sodium current. Although sodium channel blockade initially was believed to be the sole cause of systemic toxicity, mechanisms are more complex, especially in the heart, and may occur at systemic concentrations lower than previously thought.⁷² Local anesthetics may interact with other cellular systems at clinically relevant concentrations. For example, lidocaine inhibited muscarinic signaling in *Xenopus* oocytes at less than 50% of the concentration required for sodium channel blockade.⁵⁰ Growing evidence indicates that local anesthetics can directly affect many other organ systems and functions such as the coagulation, immune, and respiratory systems, all at concentrations much lower than those required to achieve sodium channel blockade.^{17,49,50} Study of these less well-described effects may help elucidate both therapeutic and toxic phenomena that are incompletely explained.

The primary determinant of the onset of action of a local anesthetic is its pK_a , which affects the lipophilicity of a drug ([Table 67–1](#)). All the local anesthetics are weak bases, with a pK_a between 7.8 and 9.3. At physiologic pH (7.4), xenobiotics with a lower pK_a have more uncharged molecules that are free to cross the nerve cell membrane, producing a faster onset of action than xenobiotics with a higher pK_a . The onset of action also is influenced by the total dose of local anesthetic administered, which affects the concentration responsible for diffusion.

TABLE 67–1. Pharmacologic Properties of Local Anesthetics^{48,100}

	pK_a	Protein Binding (%)	Log D^a	Relative Potency	Duration of Action	Approximate Maximum Allowable Subcutaneous Dose (mg/kg)
Esters						
Chloroprocaine	9.3	Unknown	1.17	Intermediate	Short	10
Cocaine	8.7	92	1.14	Low	Medium	3
Procaine	9.1	5	0.72	Low	Short	10
Tetracaine	8.4	76	2.23	High	Long	3
Amides						
Bupivacaine	8.1	95	2.45	High	Long	2
Etidocaine	7.9	95	3.16 ^b	High	Long	4
Lidocaine	7.8	70	2.36	Low	Medium	4.5
Mepivacaine	7.9	75	0.93	Intermediate	Medium	4.5
Prilocaine	8.0	40	0.75	Intermediate	Medium	8
Ropivacaine	8.2	95	1.92	Intermediate	Long	2–3

^aLog D is the octanol/water partition coefficient at a pH of 7. ^bLog D for etidocaine is at a pH of 7.4.

Local anesthetic potency is highly correlated with the lipid solubility of the xenobiotic. Therefore, the aromatic side of the anesthetic is the primary determinant of potency. The hydrophilic amine is important in occupying the sodium channel, which involves an ionic interaction with the charged form of the tertiary amine. The length of the intermediate chain is another determinant of local anesthetic activity, with three to seven carbon equivalents providing maximal activity.²³ Shorter or longer intermediate chain lengths are associated with rapid loss of local anesthetic action, suggesting that a critical length of physical separation of the aromatic group from the tertiary amine is required for sodium channel blockade to occur.

The degree of protein binding influences the duration of action of a local anesthetic. Anesthetics with greater protein binding remain associated with the neural membrane for a longer time interval and therefore have longer durations of action.²³ When high serum concentrations are achieved, a higher degree of protein binding increases the risk for cardiac toxicity.

PHARMACOKINETICS

A distinction must be made between local disposition (distribution and elimination) and systemic disposition of the anesthetic. Local distribution is influenced by several factors, including spread of local anesthetic by bulk flow, diffusion, transport via adjacent blood vessels, and binding to proximate tissues. Local elimination occurs through systemic absorption, transfer into the general circulation, and local hydrolysis of amino ester anesthetics. Systemic absorption decreases the amount of local anesthetic that is available for anesthetic effect, thereby limiting the duration of the block. Systemic absorption depends on the avidity of binding of local anesthetics to tissues near the site of injection and on local perfusion. Both these factors vary with the site of injection. In general, areas with greater blood flow will have more rapid and complete systemic uptake of local anesthetic, for example, intravenous (IV) > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous.

Because of their lipophilicity, local anesthetics readily cross cell membranes, the blood–brain barrier, and the placenta. After being absorbed, systemic tissue distribution is highly dependent on tissue perfusion. After local anesthetics enter into the venous circulation, they pass through the lungs, where significant uptake may occur, thereby lowering peak arterial concentrations. Thus, the lungs may serve as a buffer against systemic toxicity,⁶³ but the capacity of the lungs to accumulate drug is saturable. Part of the reason why most local anesthetic–induced seizures result from unintentional intravascular bolus injection rather than absorptive uptake is that lung uptake of these drugs exceeds 90%. The very high peak venous concentrations produced by rapid injection usually are necessary to produce toxic arterial concentrations.

All local anesthetics, except cocaine, cause peripheral vasodilation by direct relaxation of vascular smooth muscle. Vasodilation enhances vascular absorption of the local anesthetic. Addition of epinephrine (5 µg/mL or 1:200,000) to the local anesthetic solution decreases the rate of vascular absorption, thereby improving the depth and prolonging the duration of local action. Local anesthetic mixed with epinephrine also decreases bleeding into the surgical field and serves as a marker for inadvertent intravascular injection (by producing tachycardia) when a test dose of the mixture is injected through a needle or catheter.⁷⁶

Significant drawbacks to epinephrine use include uncomfortable side effects such as palpitations and tremors, local tissue ischemia, and life-threatening systemic adverse reactions in susceptible patients (eg, myocardial ischemia and

hypertensive crises). Inadvertent intravascular injection of local anesthetics mixed with epinephrine can be fatal, although generally the epinephrine in these mixtures is very dilute.⁶⁷

The two classes of local anesthetics undergo metabolism by different routes (Chap. 78). The amino esters are rapidly metabolized by plasma cholinesterase to the major metabolite, PABA. The amino amides are metabolized more slowly in the liver to a variety of metabolites that do not include PABA.²² Patients with enzymatic mutations, low or absent concentrations of plasma cholinesterase or pseudocholinesterase are at increased risk for systemic toxicity from ester local anesthetics. Factors that decrease hepatic blood flow or impair hepatic function increase the risk for toxic reactions to the amino amides and make management of serious reactions more difficult. The patient's age, as it relates to liver enzyme activity and plasma protein binding, influences the rate of metabolism of local anesthetics. Whereas lidocaine's terminal half-life after IV administration averaged 80 minutes in volunteers ages 22 to 26 years, the half-life was 138 minutes in those ages 61 to 71 years⁸⁴ (Chap. 64). Newborns with immature hepatic enzyme systems have prolonged elimination of amino amides, which is associated with seizures when high continuous infusion rates are used.^{1,73} Lidocaine elimination is reduced by congestive heart failure or coadministration of xenobiotics that reduce hepatic blood flow, thus explaining the increased risk of toxicity with cimetidine and propranolol.⁹⁶ Propranolol and cimetidine also potentially decrease lidocaine clearance by inhibiting hepatic CYP450 enzymes.

Local anesthetics are often mixed to take advantage of desirable pharmacokinetics. Ideally, rapid-acting, relatively short-duration local anesthetics such as chloroprocaine or lidocaine can be combined with the longer latency, long-acting tetracaine or bupivacaine. In practice, the advantages of the mixtures are small, and toxicities are additive.⁵ Administration of one local anesthetic increases the free plasma fraction of another by displacement from protein-binding sites.⁵⁴

Local anesthetics usually cannot penetrate intact skin in sufficient quantities to produce reliable anesthesia.¹¹ Efficient skin penetration requires the combination of a high water content and a high concentration of the water-insoluble base form of the local anesthetic. This combination of properties is achieved by mixing lidocaine and prilocaine in their base forms in a 1:1 ratio (eutectic mixture of local anesthetics {EMLA}).¹⁵ Application for at least 45 minutes is required to achieve adequate dermal analgesia. Local anesthetic uptake continues for several hours during application. A liposomal formulation of 4% lidocaine (ELA-Max) facilitates skin absorption. It is as effective as EMLA for topical anesthesia.³² In addition, a 4% tetracaine gel preparation is used in children for topical skin anesthesia with an onset of action and efficacy at least as good as EMLA and without any systemic side effects.

CLINICAL MANIFESTATIONS OF TOXICITY

Although the most common adverse reactions to local anesthetics are vasovagal events associated with injection,¹¹³ the following sections focus on their local and systemic toxicity.

Toxic Reactions

Regional Side Effects and Tissue Toxicity. At a sufficient concentration, all local anesthetics are directly cytotoxic to nerve cells. However, in clinically relevant doses, they rarely produce localized nerve damage.^{58,83} Significant direct neurotoxicity may result from intrathecal injection or infusion of local anesthetics for spinal anesthesia. In this setting, lidocaine has an increased risk for both persistent lumbosacral neuropathy and a syndrome of painful but self-limited postanesthesia buttock and leg pain or dysesthesia referred to as transient neurologic symptoms.⁵³ Nerve damage often is attributed to use of excessively concentrated solutions or inappropriate formulations. Several reports of cauda equina syndrome are associated with use of hyperbaric 5% lidocaine solutions for spinal anesthesia. Hyperbaric solutions are denser than cerebrospinal fluid. This neurotoxicity appears to be a phenomenon that occurs when the anesthetic is injected through narrow-bore needles or through continuous spinal catheters. This process may result in very high local concentrations of the anesthetic that might pool around the sacral roots because of inadequate mixing.⁹⁷ The mechanism of this neurotoxicity is unknown but is believed to be independent of sodium channel blockade.⁵³ Because an equally effective block can be achieved with injection of larger volumes of lower concentration, 5% lidocaine should be avoided and bupivacaine used instead. There is a significant (up to 10-fold) increase in the development of new neurologic dysfunction after receiving a neuraxial block in patients with preexisting peripheral neuropathy a fact emphasizing informed consent.⁴⁶

Similar severe neurotoxic reactions occur after massive subarachnoid injection of chloroprocaine during attempted epidural anesthesia.⁹⁴ The neurotoxicity initially appeared to be associated with use of the antioxidant sodium bisulfite and the low pH of the commercial solution rather than use of the anesthetic itself.¹¹⁵ Although chloroprocaine has been reformulated without bisulfite, new animal data suggest that it is the anesthetic itself that may be responsible for the neurotoxicity.¹¹¹ Skeletal muscle changes are observed after intramuscular injection of local anesthetics, especially the more potent, longer acting xenobiotics. The effect is reversible, and muscle regeneration is complete within 2 weeks after injection of local anesthetics.⁸

Although rare, transient or prolonged postoperative neuropathy after peripheral nerve or plexus block is well recognized. Likely mechanisms include direct injury of the nerve related to intraneuronal injection and local anesthetic neurotoxicity. The frequency of peripheral neuropathies reported after peripheral nerve blockade varies from 0% to more than 5%.¹² The use of ultrasound guidance to direct needle position may reduce this complication because of direct visualization of the peripheral nerve, avoiding traumatic injury and allowing for injection of less local anesthetic to produce adequate nerve block. Comparative studies have shown conflicting results and were likely underpowered. Recently, analysis of 12,868 ultrasound-guided nerve blocks for peripheral regional anesthesia found that the incidences of postoperative neurologic symptoms lasting longer than 5 days and 6 months were 0.18% and 0.008%, respectively.¹⁰⁵ Visualization of the target site via ultrasound guidance may well be shown to also decrease local anesthetic systemic toxicity by averting inadvertent intravascular injection.

Systemic Side Effects and Toxicity

Allergic Reactions. Allergic reactions to local anesthetics are extremely rare. Fewer than 1% of all adverse drug reactions caused by local anesthetics are immunoglobulin (Ig) E mediated.⁴⁰ In one study designed to determine the prevalence of true local anesthetic allergy in patients referred to an allergy clinic for suspected hypersensitivity, skin prick and intradermal testing results were negative for all 236 subjects tested.⁹ As noted, the amino esters are responsible for the majority of true allergic reactions. When hydrolyzed, the amino ester local anesthetics produce PABA, a known allergen (Chap. 55). Cross-sensitivity to other amino ester anesthetics is common. Some multidose commercial preparations of amino amides may contain the preservative methylparabens (Chap. 55), which is chemically related to PABA and is the most likely cause of the much rarer allergic reactions attributed to amino amides. Preservative-free amino amides, including lidocaine, can be used safely in patients who have reactions to drug preparations containing methylparabens unless the patient is specifically sensitive to lidocaine. Again, if the patient with a history of allergic reaction to a particular drug requires a local anesthetic, a paraben preservative-free drug from the opposite class can be chosen because there is no cross-reactivity between the amides and esters.

Methemoglobinemia. Methemoglobinemia is a frequent adverse effect of topical and oropharyngeal benzocaine and is occasionally reported with lidocaine, tetracaine, or prilocaine use. The diagnosis can be established by direct measurement of methemoglobin with a cooximeter. Most reports of methemoglobinemia associated with local anesthetics are the result of an excessive dose or a break in the normal mucosal barrier for topical anesthetics (Chap. 127).

Benzocaine is metabolized to aniline and then further metabolized to phenylhydroxylamine and nitrobenzene, which are both potent oxidizing agents (Chap. 127). Although reports describe methemoglobinemia resulting from standard doses of benzocaine topical oropharyngeal spray given for laryngoscopy or gastrointestinal upper endoscopy,^{30,79} affected patients commonly have abnormal mucosal integrity as occurs with thrush or mucositis. Prilocaine is an amino ester local anesthetic primarily used in obstetric anesthesia because of its rapid onset of action and low systemic toxicity in both the mother and fetus. Use of large doses of prilocaine may lead to the development of methemoglobinemia.^{48,65} Prilocaine is an aniline derivative that, when metabolized in the liver, produces ortho-toluidine, another oxidizing agent.⁴⁸ A direct relationship exists between the amount of epidural prilocaine administered and the incidence of methemoglobinemia. A dose greater than approximately 8 mg/kg is generally necessary to produce symptoms, which may not become apparent until several hours after epidural administration of the drug. EMLA cream, often used in the outpatient setting for minor dermal procedures, may result in significant methemoglobinemia, which has been reported in children and rarely in adults.⁴² Standard doses of EMLA cream used for circumcision in term neonates are associated with minimal production of methemoglobin, but risks may be increased in neonates with metabolic disorders.¹⁰⁹ When clinically indicated, affected patients with symptomatic methemoglobinemia should be treated with IV methylene blue (Chap. 127 and Antidotes in Depth: A42).

Systemic Toxicity. Systemic toxicity for all local anesthetics correlates with serum concentrations. Factors that determine the concentration include: dose; rate of administration; site of injection (absorption occurs more rapidly and completely from vascular areas, such with neck blocks and intercostal blocks); the presence or absence of a vasoconstrictor; and the degree of tissue-protein binding, fat solubility, and pK_a of the local anesthetic.⁷⁸ The brain and heart are the primary target organs for systemic toxicity because of their rich perfusion, moderate tissue-blood partition coefficients, lack of diffusion limitations, and presence of cells that rely on voltage-gated sodium channels to produce an action potential.

Recommendations for maximal local anesthetic doses designed to minimize the risk for systemic toxic reactions are published.¹⁰⁷ These maximal recommended doses aim to prevent infiltration of excessive drug. However, because most episodes of systemic toxicity from local anesthetics, with the exception of methemoglobinemia from topical drug, occur secondary to unintentional intravascular injection rather than from overdosage, limiting the maximal dose will not prevent most toxic systemic reactions.¹⁰²

Toxicity is also related to the metabolism for a given local anesthetic. The rapidity of elimination from the plasma influences the total dose delivered to the CNS or heart. The amino esters are rapidly hydrolyzed in the plasma and

eliminated, explaining their relatively low potential for systemic toxicity. The amino amides have a much greater potential for producing systemic toxicity because termination of the therapeutic effect of these drugs is achieved through redistribution and slower metabolic inactivation.³⁶ Another factor that creates difficulty in specifying the minimal toxic plasma concentration of lidocaine results from the fact that its N-dealkylated metabolites are pharmacologically active. Although these factors make it difficult to establish safe doses of local anesthetics, Table 67–2 summarizes the estimates of minimal toxic IV doses of various local anesthetics.

TABLE 67–2. Toxic Intravenous (IV) Doses of Local Anesthetics

<i>Local Anesthetic</i>	<i>Minimum IV Toxic Dose of Local Anesthetic in Humans (mg/kg)</i>
Procaine	19.2
Chlorprocaine	22.8
Tetracaine	2.5
Lidocaine	6.4
Mepivacaine	9.8
Bupivacaine	1.6
Etidocaine	3.4

Central Nervous System Toxicity. Systemic toxicity in humans usually presents with CNS abnormalities. IV infusion studies in volunteers demonstrate an inverse relationship between anesthetic potency and dose required to induce signs of CNS toxicity.¹⁰⁴ A similar relationship exists between the convulsive concentration and the relative anesthetic potency. In humans, seizures are reported at serum concentrations of approximately 2 to 4 $\mu\text{g/mL}$ for bupivacaine and etidocaine. Concentrations in excess of 10 $\mu\text{g/mL}$ are usually required for production of seizures when less potent drugs such as lidocaine are administered. Despite the strong relationship between local anesthetic potency and CNS toxicity, several other factors influence the CNS effects, including the rate of injection, drug interactions, and acid–base status.²⁵

The rapidity with which a particular serum concentration is achieved influences the toxicity of the anesthetic. Volunteers could tolerate an average dose of 236 mg of etidocaine and a serum concentration of 3 $\mu\text{g/mL}$ before onset of CNS symptoms when the anesthetic was infused at a rate of 10 mg/min. However, when the infusion rate was increased to 20 mg/min, the same individuals could tolerate only an average of 161 mg of the drug, which produced a serum concentration of approximately 2 $\mu\text{g/mL}$.¹⁰³

Centrally acting local anesthetics can modify the clinical presentation of a systemic toxic reaction. In general, CNS-depressant drugs minimize the signs and symptoms of CNS excitation and increase the threshold for local anesthetic–induced seizures. Flumazenil increases the sensitivity of the CNS to the amino amide anesthetics.¹⁴

Both metabolic and respiratory acidoses increase local anesthetic–induced CNS toxicity. Acidemia decreases plasma protein binding, increasing the amount of free drug available for CNS diffusion despite promoting the charged form of the amine group. The convulsive threshold of various local anesthetics is inversely related to arterial PCO_2 .^{27,33,34} Hypercarbia may lower the seizure threshold by several mechanisms: (1) increased cerebral blood flow, which increases drug delivery to the CNS; (2) increased conversion of the drug base to the active cation in the presence of decreased intracellular pH; and (3) decreased plasma protein binding, which increases the amount of free drug available for diffusion into the brain.^{16,27,33,34}

A gradually increasing serum lidocaine concentration usually produces a stereotypical pattern of symptoms and signs (Fig. 67–3). In an awake patient, the initial effects include tinnitus, lightheadedness, circumoral numbness, disorientation, confusion, auditory and visual disturbances, and lethargy. Subjective side effects occur at serum concentrations between 3 and 6 $\mu\text{g/mL}$. Significant psychological effects of local anesthetics are also reported. Near-death experiences and delusions of actual death are described as specific symptoms of local anesthetic toxicity.⁶⁸ Thus, the appearance of psychological symptoms during administration of local anesthetics should not be disregarded as unrelated nervous reactions or effects of sedatives given as premedication but rather as a possible early sign of CNS toxicity.

FIGURE 67–3. Relationship of signs and symptoms of toxicity to serum lidocaine concentrations.

Clinical signs, usually excitatory, then develop, and include shivering, tremors, and ultimately generalized tonic–clonic seizures. Objective CNS toxicity usually is evident at lidocaine concentrations between 5 and 9 µg/mL. Seizures may occur at concentrations above 10 µg/mL, with higher concentrations producing coma, apnea, and cardiovascular collapse. The excitatory phase has a wide range of intensity and duration, depending on the chemical properties of the local anesthetic. With the highly lipophilic, highly protein-bound drugs, the excitement phase is brief and mild. Toxicity from a large IV bolus of bupivacaine may present without any CNS excitement, with bradycardia, cyanosis, and coma as the first signs.⁹⁹ Rapid intravascular injection of lidocaine may produce a brief excitatory phase followed by generalized CNS depression with respiratory arrest. Seizures may follow even a small dose injected into the vertebral or carotid artery (as may occur during stellate ganglion block).⁵⁷ A relative overdose produces a slower onset of effects (usually within 5–15 minutes of drug injection), with irritability progressing to seizures.

The mechanism of the initial CNS excitation involves a selective block of cerebral cortical inhibitory pathways in the amygdala.^{110,114} The resulting increase in unopposed excitatory activity leads to seizures. As the concentration increases further, both inhibitory and excitatory neurons are blocked, and generalized CNS depression ensues.

Treatment of Local Anesthetic Central Nervous System Toxicity

At the first sign of possible CNS toxicity, administration of the drug must be discontinued. One hundred percent oxygen should be supplied immediately, and ventilation should be supported if necessary. Patients with minor symptoms usually do not require treatment, provided adequate respiratory and cardiovascular functions are maintained. The patient must be followed closely so that progression to more severe effects can be detected.

Although most seizures caused by local anesthetics are self-limited, they should be treated quickly because the hypoxia and acidemia produced by prolonged seizures may increase both CNS and cardiovascular toxicity.^{80,82} Intubation is not mandatory, and the decision to intubate must be individualized. Maintaining adequate ventilation is of proven value, but modest hyperventilation, in theory, might decrease CNS toxicity. By decreasing CNS extraction of drug, lowering extracellular potassium, and hyperpolarizing the neuronal cell membrane, normalizing (lowering) PCO₂ may decrease the affinity or accelerate separation of the local anesthetic from the sodium channel. Ultra-short-acting barbiturates and benzodiazepines have been used for treatment of local anesthetic–induced seizures, but either of these medication groups can also exacerbate circulatory and respiratory depression.^{25,75} Propofol 1 mg/kg IV was as effective as thiopental 2 mg/kg IV in stopping bupivacaine induced seizures in rats and has been used successfully in a patient with uncontrolled muscle twitching secondary to local anesthetic toxicity.^{10,44} However, propofol may cause significant bradydysrhythmias and even asystole, especially when used with other xenobiotics that cause bradycardia. Whether propofol interacts with local anesthetics to enhance their bradydysrhythmic effects is not known, and it is not possible to generally recommend propofol over benzodiazepines for treatment of local anesthetic CNS toxicity. Neuromuscular blockers are proposed as adjunctive treatment for local anesthetic induced seizures. They block muscular activity, decreasing oxygen demand and lactic acid production. However, neuromuscular blockers should never be used to treat seizures per se because they have no anticonvulsant effect and can make clinical diagnosis of ongoing seizures problematic by abolishing muscle contractions. To avoid this potentially lethal complication, chemical paralysis should be used only to facilitate endotracheal intubation if needed, unless continuous electroencephalography is also used. If used, short-acting neuromuscular blockers are desirable, facilitating subsequent repeated neurologic assessments. Succinylcholine may not be ideal because of its significant side effects, including hyperkalemia and dysrhythmias. The use of nondepolarizing neuromuscular blockers with less potential

for cardiac side effects, such as rocuronium, should be considered (Chap. 69).

When severe systemic toxicity occurs, the cardiovascular system must be monitored closely because cardiovascular depression may go unnoticed while seizures are being treated. Because local anesthetic–induced myocardial depression may occur even with preserved blood pressure, it is important to be aware of early signs of cardiac toxicity, including electrocardiographic (ECG) changes.

If toxicity results from ingestion of liquid medications, as most are, activated charcoal is generally indicated, but benefits are unproven. If the patient presents immediately after ingestion, gastric lavage with a nasogastric tube may be considered. Induction of emesis is contraindicated even after oral administration because of the risk of seizures and aspiration. Contaminated mucous membranes should be washed off. Hemodialysis is not of proven utility and may be impractical, as is hemoperfusion.

Cardiovascular Toxicity. Cardiovascular side effects are the most feared manifestations of local anesthetic toxicity. Shock and cardiovascular collapse may be related to effects on vascular tone, inotropy, and dysrhythmias related to indirect CNS and direct cardiac and vascular effects of the local anesthetic. Animal studies and clinical observations clearly demonstrate that for most local anesthetics, CNS toxicity develops at significantly lower serum concentrations (exception: bupivacaine) than those needed to produce cardiac toxicity, that is, they have a high cardiovascular:CNS toxicity ratio.^{57,81,82,99} When cardiac toxicity occurs, management may be exceedingly difficult. Some of the discrepancy between the incidence of CNS and cardiac toxicity may result from a detection bias. Not only can the treating physicians fail to recognize cardiac effects because of preoccupation with CNS manifestations of toxicity, but early cardiac toxicity may be quite subtle. An experimental study attempting to identify early warning signs of bupivacaine-induced cardiac toxicity in pigs evaluated bupivacaine-induced changes in cardiac output, heart rate, blood pressure, and ECG.⁸⁸ A 40% reduction in cardiac output was not associated with significant change in heart rate or blood pressure, the latter secondary to a direct vasoconstrictive effect of bupivacaine at the concentrations produced.¹⁸

Changes in systemic vascular tone induced by local anesthetics may be mediated by direct effect on vascular smooth muscle or indirectly via effects on spinal cord sympathetic outflow. Predictably, sympathetic blockade after spinal anesthesia or epidural anesthesia above the T5 dermatome results in peripheral venodilation and arterial dilation. Shock may result when high doses of anesthetic are used in hypovolemic patients. Local anesthetics have a biphasic effect on peripheral vascular smooth muscle. Whereas lower doses produce direct vasoconstriction, higher doses are associated with severe cardiovascular toxicity and cause vasodilation, contributing to cardiovascular collapse.

All local anesthetics directly produce a dose dependent decrease in cardiac contractility, with the effects roughly proportional to their peripheral anesthetic effect. Although the classic anesthetic action of sodium channel blockade in heart muscle accounts in large part for the negative inotropy by affecting excitation–contraction coupling, it does not explain the entire difference in myocardial depression produced by different anesthetics.²⁸ Poorly understood effects on calcium handling or effects of the intracellular drug directly on contractile proteins or mitochondrial function may be operable.²⁸

Blockade of the fast sodium channels of cardiac myocytes decreases maximum upstroke velocity (V_{\max}) of the action potential (Chaps. 16 and 17 and Fig. 64–1). This effect slows impulse conduction in the sinoatrial and atrioventricular (AV) nodes, the His-Purkinje system, and atrial and ventricular muscle.²¹ These changes are reflected on ECG by increases in PR interval and QRS duration. At progressively higher anesthetic concentrations, hypotension, sinus arrest with junctional rhythm, and eventually cardiac arrest occur.⁴ Asystole has been described in patients who received unintentional IV bolus injections of 800 to 1000 mg of lidocaine.^{4,35} Cardiovascular toxicity of local anesthetics usually occurs after a sudden increase in serum concentration, as in unintentional intravascular injection. Cardiovascular toxicity is rare in other circumstances because high serum concentrations are necessary to produce this effect and because CNS toxicity precedes cardiovascular events, providing a warning. Cardiac toxicity usually is not observed with lidocaine use in humans until the serum lidocaine concentration greatly exceeds 10 $\mu\text{g/mL}$ unless the patient is also receiving xenobiotics that depress sinus and AV nodal conduction such as calcium channel blockers, β -adrenergic antagonists, or cardioactive steroids.

Bupivacaine is significantly more cardiotoxic than most other local anesthetics commonly used. Inadvertent intravascular injection produces near simultaneous signs of CNS and cardiovascular toxicity.

Animal studies have compared the dose or serum concentrations of local anesthetics required to produce irreversible circulatory collapse with those necessary to produce seizures.^{26,81,82} This cardiovascular collapse:CNS toxicity (CC:CNS) ratio for lidocaine is approximately 7; therefore, CNS toxicity should become evident well before potentially cardiotoxic concentrations are reached. In contrast, the CC:CNS ratio for bupivacaine is 3:7. Bupivacaine produces myocardial depression out of proportion to its anesthetic potency and, more important, may cause refractory ventricular dysrhythmias.¹⁰¹ Enhanced cardiovascular toxicity may relate to enhanced CNS effects at cardiovascular centers,¹¹² direct effects on myocyte metabolism, and important differences related to sodium channel blockade. Although lidocaine and bupivacaine both block sodium channels in the open or inactivated states, lidocaine quickly dissociates from the channel at diastolic potentials, allowing rapid recovery from block during diastole (fast on–fast off). Therefore, sodium channel blockade with lidocaine is much more pronounced at rapid heart rates (accounting for the antidysrhythmic effects for ventricular tachycardia).⁶⁷ On the other hand, at high concentrations, bupivacaine rapidly binds to and slowly dissociates

from sodium channels (fast on–slow off), with significant block accumulating at all physiologic heart rates.²¹ Accordingly, at heart rates of 60 to 150 beats/min, approximately 70 times more lidocaine is needed than bupivacaine to produce an equal effect on V_{\max} of the action potential. Enhanced conduction block in Purkinje fibers and ventricular muscle cells sets up a reentrant circuit responsible for the ventricular tachydysrhythmias induced by bupivacaine.⁷⁴

Bupivacaine, a potent and long-acting amide anesthetic, not only has the highest potential for cardiovascular toxicity, but these effects are quite refractory to conventional therapy. Bupivacaine has an asymmetrically substituted carbon, and the kinetics of sodium channel binding are stereospecific.⁶⁰ The S (levo)-enantiomer levobupivacaine is significantly less cardiotoxic than the R (dextro)-enantiomer despite having similar anesthetic properties.^{6,72} Consequently, bupivacaine, the racemic mixture of both enantiomers, is more cardiotoxic than levobupivacaine, which contains only the levo-enantiomer.⁴¹ The stereospecific effect on sodium channels seems to differ between the heart and the peripheral nerves because the local anesthetic potency of levobupivacaine is the same as, or perhaps even greater than, that of bupivacaine.^{31,85} Ropivacaine is a pure enantiomer and is less cardiotoxic than bupivacaine, but it is also slightly less potent as an anesthetic.^{91,92}

Effects other than sodium channel blockade may contribute to cardiotoxicity. Lipophilic local anesthetics such as bupivacaine may directly impair mitochondrial energy transduction via two mechanisms: (1) uncoupling of oxygen consumption and adenosine triphosphate (ATP) synthesis and (2) inhibition of complex I in the respiratory chain.¹⁰¹ This effect is related to the lipophilic properties of the drug rather than to stereospecific effects on ion channels. Lidocaine has no effect on mitochondrial respiration, and ropivacaine has less effect than bupivacaine.¹²¹ There is no difference between the two bupivacaine enantiomers. These effects occur with higher concentrations of the local anesthetic, as occur after unintentional intravascular injection.

Low dose bupivacaine-induced cardiotoxic effects are described in humans under certain circumstances and at concentrations that are not associated with seizure activity in pigs.^{55,120} Severe cardiac toxicity is described after injection of a small subcutaneous dose of bupivacaine in a patient with secondary carnitine deficiency.¹²⁰ Myocytes are highly dependent on oxidation of free fatty acids for energy. Interference with this mechanism via bupivacaine-induced inhibition of carnitine-acylcarnitine translocase has been proposed to contribute to the cardiotoxicity of lipophilic local anesthetics¹²⁰ (Chap. 48, Fig. 48–2, and Antidotes in Depth: A20). Bupivacaine may produce dysrhythmias by blocking GABAergic neurons that tonically inhibit the autonomic nervous system.⁴⁵ In addition to its other effects on the heart, bupivacaine may induce a marked decrease in cardiac contractility by altering Ca^{2+} release from sarcoplasmic reticulum.⁶⁶

In a large series of patients receiving bupivacaine, systemic toxicity occurred in only 15 of 11,080 nerve blocks.⁷⁷ Of these patients, 80% convulsed; the other 20% had milder symptoms. A series of cases was described in which bupivacaine use, particularly at 0.75% concentration, was associated with severe cardiovascular depression, ventricular dysrhythmias, and even death. Pregnant women were disproportionately affected. Some of these patients required prolonged resuscitation, and restoration of adequate spontaneous circulation proved exceedingly difficult.⁹⁵ In 1983, 49 incidents of cardiac arrest or ventricular tachycardia that occurred over a 10-year period were presented to the US FDA Anesthetic and Life Support Advisory Committee. Among these cases, 0.75% bupivacaine was used in 27 obstetric patients with 10 deaths, and 0.5% bupivacaine was used in 8 obstetric patients with 6 deaths. Among the 14 nonobstetric patients, 5 died. The overall mortality rate was 21 of 49 (43%). Partly as a result of these reports, in 1984, the FDA withdrew approval of bupivacaine 0.75% for use as obstetric anesthesia.⁹⁵

Acid–base and electrolyte status influence the cardiac toxicity of a given drug because all depressant properties are potentiated by acidosis, hypoxia, or hypercarbia.¹³ Table 67–3 outlines the spectrum of acute local anesthetic reactions.

TABLE 67–3. Types of Local Anesthetic Reactions

<i>Cause</i>	<i>Major Clinical Features</i>
Local anesthetic toxicity (intravascular injection)	Immediate seizure or dysrhythmias
Reaction to catecholamine	Tachycardia, hypertension, headache
Vasovagal reaction	Bradycardia, rapid onset and recovery, hypotension, pallor
Allergic reaction	Anaphylaxis
High spinal or epidural block	Bradycardia, hypotension, respiratory distress, respiratory arrest

LABORATORY STUDIES

In cases of possible local anesthetic toxicity, an ECG should be obtained to detect dysrhythmias and conduction disturbances. Serum electrolytes, blood urea nitrogen, creatinine, and a blood gas analysis should be obtained to help assess the cause of cardiac dysrhythmias. Cooximetry should be obtained in patients in whom methemoglobinemia is suspected clinically. Rapid, sensitive assays are available for measuring concentrations of lidocaine and its monoethylglycylxylidide (MEGX) metabolite. When properly interpreted, the results of these assays may be used to prevent lidocaine toxicity and to identify lidocaine toxicity in the nontherapeutic setting. Assays for determining serum concentrations of other local anesthetics are not routinely available. Treatment should never be delayed while waiting for results of xenobiotic concentration determinations.

TREATMENT

Treatment of Local Anesthetic Cardiac Toxicity

Treatment of cardiovascular complications of local anesthetics is complicated by the complex effects of local anesthetics on the heart. Initial therapy should focus on correcting the physiologic derangements that may potentiate the cardiac toxicity of local anesthetics, including hypoxemia, acidemia, and hyperkalemia.^{13,98} Prompt support of ventilation and circulation limits hypoxia and acidemia. Early recognition of potential cardiac toxicity is critical to achieving a good outcome because patients with cardiac toxicity that goes unrecognized for any interval are more difficult to resuscitate.⁷ If a potentially massive intravascular local anesthetic injection is suspected, maximizing oxygenation of the patient before cardiovascular collapse occurs is critical.

Intravenous Fat Emulsion

While investigating the relationship between lipid metabolism and bupivacaine toxicity (described earlier), a rat study of bupivacaine induced asystolic arrest showed that pretreatment with IV fat emulsion (IFE) increased the dose of bupivacaine by 50% that was necessary to induce toxicity.¹²² In addition, a dose of bupivacaine that was uniformly fatal in control rats resulted in universal survival in animals that also received fat emulsion.¹²² Subsequent studies of local anesthetic toxicity have demonstrated accelerated return of cardiac function after IFE both in intact animals and in isolated hearts.^{117,118}

In clinical reports, epinephrine has limited efficacy in the treatment of cardiac arrest that results from bupivacaine toxicity. This could possibly be secondary to inhibition of intracellular cyclic adenosine monophosphate production by bupivacaine. The efficacy of IFE was demonstrated when compared with epinephrine for resuscitation of bupivacaine induced cardiovascular collapse in a rodent model.¹¹⁹

An infusion of a 20% IFE was successfully used to resuscitate a patient from a prolonged cardiac arrest caused by bupivacaine toxicity. The patient rapidly stabilized with IFE after failing to improve with 20 minutes of advanced cardiopulmonary resuscitation (CPR).¹⁰⁰ Subsequently, several case reports have been published describing successful use of IFE (in various formulations) to treat patients in cardiac arrest after regional anesthesia with various local anesthetics including bupivacaine, ropivacaine, and levobupivacaine.^{52,62,116} Although the majority of reports and potential mechanisms of action (see later discussion) suggest that IFE would be most useful in the treatment of systemic effects of lipid-soluble local anesthetics, a recent case report documents reversal of severe neurotoxicity related to lidocaine, which is far less lipophilic.⁵⁹ However, when lipid solubility is expressed as the octanol/water partition coefficient at physiologic pH (Log D), it becomes clear that lidocaine toxicity should be amenable to treatment with IFE (Table 67–1).

The mechanism by which IFE reverses local anesthetic toxicity is uncertain. One of the hypotheses is that the exogenous fat emulsion provides a competing source for binding of lipid-soluble local anesthetics, a circulating lipid sink. This view is supported by a study that demonstrated decreased cardiac bupivacaine concentrations after IFE.¹¹⁸ Another possibility is that the fat emulsion load might overwhelm the inhibition of the carnitine acylcarnitine translocase by mass action, increasing mitochondrial free fatty acids, thereby increasing myocardial energy production, making the heart more likely to respond to resuscitation. In isolated guinea pig heart preparations exposed to high concentrations of bupivacaine and ropivacaine for 10 minutes, cardiomyocyte mitochondria had reduced oxygen consumption and concentration dependent morphologic swelling.⁴⁷ Because the brain does not use lipid for energy production and IFE can reverse local anesthetic CNS toxicity, nonmetabolic processes are clearly involved.⁸⁹ For example, IFE has positive inotropic effects in isolated heart preparations and reversed bupivacaine-induced cardiac depression at lipid concentrations less than those needed to reduce aqueous bupivacaine concentration.¹⁰⁶

Increasing clinical data suggest that an IV bolus of fat emulsion may be lifesaving in patients with refractory cardiovascular collapse secondary to local anesthetic overdose. Twenty-two peer-reviewed case reports from 2006 to 2011 describe the effective use of IFE in local anesthetic systemic toxicity.⁸⁹ Thirteen of the cases involve bupivacaine. Although optimal dosing is uncertain,¹¹⁰ based on accumulating experience, the use of IFE for local anesthetic systemic toxicity has been endorsed by multiple organizations, including the American Society of Regional Anesthesia and Pain

Medicine (ASRA) and the American College of Medical Toxicology. The most recent and detailed guidelines by the ASRA⁸⁶ suggest dosing for a patient in cardiac arrest is 1.5 mL/kg bolus of 20% IFE over one minute while continuing chest compressions followed by continuous infusion of 0.25 mL/kg/min. For persistent cardiovascular collapse, the bolus may be repeated once or twice, and the infusion rate should be doubled. If there is evidence of recovery, the infusion should be continued for at least 10 minutes after stability. IFE should be given after signs of local anesthetic toxicity become manifest¹²³ (Antidotes in Depth: A20).

In addition to lipid therapy, standard advanced cardiac life support (ACLS) protocols should be followed when dealing with most local anesthetic cardiac toxicity. Hypotension in sinus rhythm results from both peripheral vasodilation and myocardial depression and should be treated with α - and β -adrenergic agonists. Atropine supplemented with electrical pacing should be used to treat bradycardia. The effectiveness of epinephrine in reversing local anesthetic-induced cardiac depression is variable in animal models, and the ASRA guidelines recommend using only small doses (eg, $<1 \mu\text{g/kg}$) for hypotension in this setting. The dysrhythmic effects of epinephrine are of particular concern. Amrinone (currently inamrinone), a phosphodiesterase III inhibitor, was evaluated for treatment of bupivacaine-induced cardiac toxicity.^{39,61} Anesthetized pigs with cardiovascular collapse induced by bupivacaine infusion survived when they were treated with amrinone; all the control animals died of irreversible cardiac arrest.⁶¹ An IV phosphodiesterase III inhibitor, milrinone is the most available and would be a good choice for reversing bupivacaine-induced cardiac depression.¹⁰⁴ An infusion of 0.375 to 0.75 $\mu\text{g/kg/min}$ (without a loading dose), with adjustments for renal insufficiency, should be considered.

Bupivacaine-induced dysrhythmias often are refractory to cardioversion, defibrillation, and pharmacologic treatment. Lidocaine, phenytoin, magnesium, bretylium, amiodarone, calcium channel blockers, and combined therapy with clonidine and dobutamine have all been used in animal models with variable results.^{29,69,71} Therapy for bupivacaine toxicity should be directed toward dissociating bupivacaine from the myocardial sodium channel, thereby reversing the drug's effects on cardiac conduction. Lidocaine competes with bupivacaine for cardiac sodium channels and at high doses may displace it. Anecdotal reports suggest that lidocaine has occasionally helped in this application.²⁴ However, concern persists about additive CNS effects when lidocaine is used to treat bupivacaine cardiac toxicity, and the guidelines suggest avoidance of calcium channel blockers, β -adrenergic antagonists, and local anesthetics.

With toxicity from the longer acting, highly lipid-soluble, protein-bound amide local anesthetics (bupivacaine and etidocaine), if the patient does not respond promptly to therapy, CPR can be expected to be difficult and prolonged (1–2 hours) before depression of the cardiac conduction system spontaneously reverses as a result of redistribution and metabolism of the drugs.^{2,93} Vital organ perfusion is seriously compromised during CPR despite optimal chest compression. The significance of this problem increases with the duration of resuscitation; therefore, rapid initiation of cardiopulmonary bypass should be considered if practical. Its use has resulted in a successful outcome in some cases of lidocaine and bupivacaine overdose.^{38,64} Cardiopulmonary bypass provides circulatory support that is far superior to that provided by closed-chest cardiac massage. The improved perfusion prevents tissue hypoxia and the development of metabolic acidosis, which in turn decreases the binding of local anesthetics to myocardial sodium channel receptors. Hepatic blood flow is better maintained, enhancing local anesthetic metabolism, and increased myocardial blood flow helps redistribute local anesthetics out of the myocardium.⁶⁴

Cardiac pacing was used successfully for treatment of cardiac arrest after unintentional administration of a 2 g bolus of lidocaine into a cardiopulmonary bypass circuit as the patient was being removed from bypass.⁸⁷ Pharmacologic therapy was unsuccessful, and resumption of bypass was necessary. Forty-five minutes after the injection, AV pacing restored perfusion and permitted discontinuation of bypass.

Use of sodium bicarbonate early in resuscitation to prevent acidemia mediated potentiation of cardiac toxicity may have been beneficial in some cases,²⁴ but paradoxical effects on intracellular pH during CPR argue against its use in the absence of strong experimental or clinical data. In another canine model, an infusion of 2 mL/kg 50% dextrose plus 1 unit/kg insulin was superior to saline or dextrose alone in reversing bupivacaine-induced cardiac depression²⁰ (Antidotes in Depth: A17). Effects on potassium current, calcium handling, and myocardial energy utilization (by providing an alternative energy substrate) all may have contributed to the salutatory effects of the insulin infusion.

Prevention of Systemic Toxicity of Local Anesthetics

Despite the development of new, relatively less toxic amide local anesthetics such as levobupivacaine and ropivacaine, severe CNS and cardiovascular effects remain a risk. Several cases of ropivacaine induced cardiac arrest are reported.^{19,52,56} In these cases, patients with both asystolic arrest and ventricular fibrillation associated arrest were successfully resuscitated. Nonetheless, it is clear that prevention is more prudent and effective than treatment of toxicity. The keys to prevention are to use the lowest possible anesthetic concentration and volume consistent with effective anesthesia and to avoid a significant intravascular injection. The latter is accomplished by ensuring extravascular placement demonstrated repetitively by ultrasonographic guidance and by careful, slow aspiration of a needle or catheter before injection; injection of a small test dose of anesthetic mixed with epinephrine to assess a cardiovascular response if injection is intravascular; and use of slow, fractional dosing of large-volume injections with vigilance for early signs of

CNS and cardiac toxicity.

SUMMARY

- Local anesthetics are frequently used xenobiotics that provide surgical analgesia and acute and chronic pain relief.
- The analgesic effect of local anesthetics is primarily caused by inhibition of neural conductance secondary to sodium channel blockade.
- Systemic toxicity, which primarily affects the heart and brain, is also largely related to sodium channel blockade.
- Severe systemic toxicity usually occurs secondary to inadvertent intravascular injection.
- If cardiovascular collapse and cardiac arrest occur, especially in the setting of bupivacaine toxicity, resuscitation may be difficult and prolonged. A novel therapy, IFE, has been shown to reverse, by uncertain mechanisms, local anesthetic toxicity.
- Cardiopulmonary bypass may be useful because it provides cardiovascular support, limits exacerbating factors such as tissue hypoxia and acidemia, and improves hepatic blood flow, thereby increasing local anesthetic metabolism.

A20 ANTIDOTES IN DEPTH

Intravenous Fat Emulsion

Theodore C. Bania

INTRODUCTION

The use of intravenous fat emulsion (IFE) as an antidote is most extensively studied for the treatment of local anesthetic systemic toxicity. However, new applications that are being investigated and reported include the treatment of overdose from lipophilic xenobiotics such as calcium channel blockers, cyclic antidepressants, and β -adrenergic antagonists, among others.

HISTORY

IFE has been used as a source of parenteral nutrition for over 40 years and is also used as a diluent for intravenous drug delivery of highly lipophilic xenobiotics such as amphotericin and propofol. Recently, liposomal suspensions containing local anesthetics such as bupivacaine have been formulated that slowly release xenobiotics to increase the duration of anesthetic effect.

Although rare, bupivacaine toxicity is usually refractory to standard cardiac resuscitative measures ([Chap. 67](#)). In the setting of cardiovascular collapse, fatalities are frequent. Previously, cardiopulmonary bypass was the only effective treatment for these patients, as most cases were unresponsive to less invasive therapy. IFE was first evaluated in several animal models and was successful for the treatment of bupivacaine toxicity. Because of the success in animal models and the ineffectiveness of other therapies, IFE was attempted in humans and multiple case reports document apparent benefit. Subsequently, IFE was recommended by several anesthesia specialty societies for the treatment of local anesthetic toxicity. The initial proposed mechanism of action of IFE is the binding of local anesthetic in the serum lipid phase and decreasing the amount of xenobiotic at the site of toxicity. Subsequently, IFE was evaluated in several animal models of toxicity from lipid soluble xenobiotics. Based on these studies, IFE was used in several case reports of poisoning.

PHARMACOLOGY

Chemistry/Preparation

IFE is composed of two types of lipids: triglycerides and phospholipids. Triglycerides are hydrophobic molecules that are formed when three fatty acids are linked to one glycerol. The fatty acid chain lengths vary, producing different triglycerides. The primary triglycerides in IFE are linoleic, linolenic, oleic, palmitic, and stearic acids; their concentrations vary slightly in the different commercially available fat emulsions. These long-chain triglycerides (12 or more carbons) are extracted from safflower oil and/or soybean oil, depending on the brand of the emulsion.⁷⁹ Newer fat emulsions contain long-chain triglycerides in addition to medium-chain triglycerides (6–12 carbons) derived from coconut, olive, and fish oils, but they are currently not available in the United States.^{54,84}

Phospholipids contain two fatty acids bound to glycerol and a phosphoric acid moiety that is located at the third hydroxyl group ([Fig. A20–1](#)). Phospholipids are amphipathic; that is, the nonpolar fatty acids are hydrophobic while the polar phosphate head is hydrophilic. This imparts important pharmacological properties to this carrier molecule, allowing it to solubilize nonpolar xenobiotics in aqueous serum. IFE phospholipids are extracted from egg yolks.

FIGURE A20–1. Biologic membranes are comprised of phospholipids that have a hydrophilic phosphoglycerol “head” and hydrophobic fatty acid “tails.”

The lipids in IFE are dispersed in the serum by forming an emulsion of small lipid droplets. To create the emulsion droplets, the phospholipids form a layer around a triglyceride core. The hydrophobic fatty acid component of the phospholipid molecule is directed toward the triglycerides while the hydrophilic glycerol component is directed outward away from the triglyceride core. The presence of small amounts of glycerol, which is hydrophilic, allows the lipid droplets to be suspended as an emulsion in water and serum.

IFE is a white, milky liquid. It is sterile and nonpyrogenic with a pH of about 8 (range, 6–9). IFEs are isoosmotic solutions (260–310 mOsm/L) and can be delivered through a peripheral or central vein.⁷⁹

IFE has different globule sizes depending on their uses.¹⁵ Microemulsions containing droplet sizes less than 0.1 µm are used for drug delivery. Mini-emulsions containing droplet sizes greater than 0.1 µm but less than 1.0 µm are used for parenteral nutrition. Droplet sizes in commercially available nutritional IFEs range from 0.4 to 0.5 µm. Phospholipid

emulsifying xenobiotics such as egg phosphatide are added and prevent droplet coalescence. After intravenous administration, IFEs are found in the serum as lipid droplets that resemble chylomicrons and turn the serum turbid or milky. Macroemulsions containing droplet sizes greater than 1.0 μm are used for chemoembolization. These macroemulsions contain chemotherapeutics that are delivered intraarterially directly into the tumor blood supply. The lipid droplets occlude the artery and slowly release the chemotherapeutic.

Related Lipid Formulations

Most case reports documenting successful treatment of local anesthetic toxicity with lipids have utilized Intralipid or standard long-chain triglyceride mixtures. IFE containing mixtures of long-chain and medium-chain triglycerides such as Medialipid (Braun, Germany) and Liposyn III (Hospira Inc., Lake Forest, IL) have been successfully used in clinical cases of poisoning, suggesting that all currently available parenteral lipid products will be effective.^{30,87} IFE containing medium-chain triglycerides are not routinely available in the United States.

Lipid emulsions containing both long-chain and medium-chain triglyceride mixtures may be more effective at partitioning xenobiotics. In human serum, a mixture of long-chain and medium-chain triglycerides increased the extraction of bupivacaine, ropivacaine, and mepivacaine compared to long-chain triglyceride mixtures.⁶⁷ However, in a rodent model of bupivacaine toxicity, long-chain and medium-chain mixtures were equally effective in reversing bupivacaine toxicity, but the long-chain mixture resulted in fewer recurrences of asystole after resuscitation and lower myocardial bupivacaine concentrations.⁴⁴

Mechanism of Action

The mechanisms of action of IFE in toxicology are not clearly understood. The three proposed mechanisms of action of IFE are modulation of intracellular metabolism, a lipid sink or sponge mechanism, and activation of ion channels.

Modulation of Intracellular Metabolism. In experimental models of poisoning from xenobiotics that alter intracellular energy metabolism, toxicity was successfully treated with IFE, suggesting that repairing or circumventing this dysfunction may be involved. Bupivacaine blocks carnitine-dependent mitochondrial lipid transport and inhibits adenosine triphosphatase (ATPase) synthetase in the electron transport chain.^{13,94} Verapamil inhibits intracellular processing of fatty acids,^{37,38} but it also inhibits insulin release and produces insulin resistance.³⁸ The cyclic antidepressant amitriptyline depresses human myocardial contraction independent of an effect on conduction³⁰ and inhibits medium- and short-chain fatty acid metabolism.⁸⁷ Propranolol changes intracellular energy from primarily fatty acid to carbohydrate-dependent metabolism.⁴⁹

Theoretically, adding excess fatty acids may overcome blocked or inhibited enzymes by mass action, providing energy to an energy “starved” heart, reversing toxicity. Some support for this mechanism comes from the IFE effect in reversing myocardial depression resulting from myocardial ischemia.⁸⁰ In a canine model employing 10 minutes of regional myocardial ischemia, treatment with IFE following ischemia resulted in improved systolic wall thickening. In the same canine model, pretreatment with oxfenicine, which blocks carnitine palmitoyltransferase-1, blocked the beneficial effect of IFE.³⁸ This finding suggests that the effects of IFE on myocardial contraction following ischemia are mediated by mitochondrial metabolism.

Unfortunately, there is limited experimental evidence to support a modulation of intracellular energy metabolism as the mechanism of action of the IFE. Some evidence comes from studies in bupivacaine toxicity. In an isolated rat heart model of bupivacaine-induced cardiotoxicity, doses of IFE in the perfusate that were too low to significantly decrease bupivacaine concentrations reversed bupivacaine-induced cardiac dysfunction.⁷⁶ Similarly, in an in vivo model of bupivacaine-induced toxicity when rodents were pretreated with a single dose of a fatty-acid oxidation inhibitor (CVT-4325), IFE was unable to rescue these rodents, implying that IFE works by providing energy in the form of free fatty acids.⁵⁹ Although these results imply that IFE works by a mechanism other than binding bupivacaine and suggest a metabolic effect, other studies support the theory that IFE works by a nonmetabolic mechanism. In one study, verapamil toxicity was induced when rodents were pretreated with the fatty acid oxidation inhibitor oxfenicine or control solution. Both groups were then resuscitated with IFE.³ There were no significant differences in survival time and mean arterial pressure between the oxfenicine-treated and control groups. Analogous to some models of bupivacaine toxicity, this study implies that in verapamil toxicity, IFE works by a mechanism other than mitochondrial energy supply.

Lipid Sink or Sponge Mechanism. In the lipid sink or sponge mechanism, IFE “soaks up” lipid-soluble xenobiotic and removes it from the site of toxicity. In a variation of this mechanism, IFE may pull the xenobiotic out of the aqueous plasma, which bathes the tissue, and into a nonaqueous part of the plasma that is not in contact with the site of toxicity. IFE may also alter the distribution of lipid-soluble xenobiotics and redistribute them away from the site of toxicity into an area with high lipid content (ie, create a “lipid conduit”). Some experimental support comes from studies of bupivacaine toxicity. In an isolated heart model, hearts perfused with bupivacaine until asystole were then treated with control or IFE. The IFE-treated hearts had a faster recovery from asystole, a lower concentration of bupivacaine in the tissue, and a higher concentrations

of bupivacaine in the venous effluent.⁹⁵ Stronger evidence for the lipid sink/sponge mechanism is seen in the effect of lipid emulsion on the pharmacokinetics and tissue distribution of bupivacaine in rats. Lipid emulsion decreased the distribution of bupivacaine into tissue, resulting in decreased concentrations in the brain and myocardium.⁷¹ Similarly, in a pharmacokinetic study of clomipramine toxicity, following IFE infusion, concentrations of clomipramine increased and volume of distribution decreased, in addition to an increase in blood pressure.²⁸ In a pharmacokinetic study of amiodarone toxicity, IFE pretreatment resulted in higher concentrations of amiodarone and higher blood pressures compared to pretreatment with saline.⁵⁸ In a well-perfused swine model, IFE decreased amitriptyline concentrations in the brain by 25% and decreased the heart-to-plasma ratio.³⁰ In a successful resuscitation from bupropion overdose, bupropion concentrations increased dramatically after IFE administration.⁸¹ Concentrations also increased following successful treatment of verapamil.¹⁹ These findings in experimental models and case reports can be explained by the lipid sink/sponge model, where IFE pulls a xenobiotic away from the site of toxicity, although the increased concentrations could be explained by an increased perfusion of tissues and release of the drug.

Additional indirect evidence supports the lipid sink/sponge and a nonmetabolic mechanism. While the myocardium can utilize fatty acids for metabolism, the central nervous system (CNS) does not use fatty acids to a substantial degree, implying that the reversal in sedation results from xenobiotic removal from the CNS as opposed to an altered metabolism. This reversal of CNS effects was demonstrated in two animal models of thiopental sedation,^{10,66} whereas in another animal model of thiopental anesthesia, IFE increased the CNS effects. These findings may support the lipid sink/sponge mechanism, as in this model it was proposed that the IFE kept serum thiopental concentration high, permitting additional thiopental diffusion into the CNS.³⁶ Reversal of CNS effects is also described in several clinical cases where the neurologic effects of bupivacaine were reversed with IFE,⁴⁸ and arousal was reported in olanzapine toxicity.⁵⁶ Additionally, a nonmetabolic effect of IFE in reversing toxicity is described in an in vitro model of methemoglobin formation. IFE added to whole blood blocked methemoglobin formation subsequent to exposure to the lipid-soluble glycerol trinitrate in a dose-dependent manner. IFE did not block methemoglobin production from non-lipid-soluble compounds such as 2-amino-5-hydroxytoluene or sodium nitrite, which supports a nonmetabolic effect of IFE and implies reversal of effect is related to lipid solubility.⁶⁹

The degree of lipid solubility of a xenobiotic can be measured using the partition coefficients log P or log D. Both measure the xenobiotic partition between a lipophilic organic phase (usually octanol) and a polar aqueous phase (usually water) and are the logarithm of the ratio of concentration of the xenobiotic between the two phases. Log P measures the partition of the nonionized form of the xenobiotic between the two phases, while log D measures the partition of both the un-ionized and the ionized form of the xenobiotic and varies based on pH. Log D can be reported across a range of pH values, and the log D at pH of 7 is considered an evaluation of lipid solubility in normal plasma. When determining if a xenobiotic is lipid soluble, the log P is most commonly reported. The log D at pH of 7 may represent a more accurate estimation of lipid solubility in a normal physiologic state, while the log D at a lower pH might more accurately represent lipid solubility during xenobiotic toxicity with hemodynamic compromise. Variations in lipid solubility may be clinically important and may alter the amount of xenobiotic partitioning into the serum lipid. In an in vitro model, the distribution of bupivacaine and ropivacaine in fat emulsion decreased at lower pH.⁵¹

Activation of Ion Channels. The mechanism of action of IFE may be the activation of, both Ca^{2+} and Na^{+} channels. Linolenic acid and stearic acid decreased bupivacaine-induced Na^{+} blockade in a human cardiac Na^{+} channel model.⁵⁵ Fatty acids directly activate myocardial Ca^{2+} channels and induce a dose-dependent increase in the Ca^{2+} current. Oleic, linoleic, and linolenic acids act directly on the Ca^{2+} channel to increase Ca^{2+} current.³²

Mechanism of Action: Conclusion. Despite the lack of definitive studies on mechanisms of action, the lipid sink/sponge model is the most likely, since beneficial effects from IFE are most frequently noted for lipid-soluble xenobiotics independent of their mechanisms of toxicity. Multiple consequential mechanisms of action may exist, and depending on the xenobiotic, the mechanism(s) of action may vary and be multifactorial.

Pharmacokinetics

Lipid droplets that are less than 1 μm are primarily removed from circulation as they pass through the capillaries of adipose and hepatic tissue. The capillary endothelium in these tissues contains lipoprotein lipase, which hydrolyzes triglycerides, releasing fatty acids and glycerol that then diffuses into the cells. Fatty acids enter the cardiac myocyte either by passive diffusion or protein-mediated transport.⁷⁵

The half-life of IFE is 30 to 60 minutes and can vary substantially depending on the patient's clinical status, IFE dose, and droplet size.¹⁷ More than 2.5 g of lipid/kg/d (12.5 mL/kg of 20% IFE or 875 mL in a 70 kg person) overwhelms lipoprotein lipase activity, resulting in decreased clearance. Larger droplet sizes have slower clearances and are removed by reticuloendothelial phagocytosis. These larger droplets are more likely to induce an inflammatory response, obstruct the microvasculature, and produce capillary fat emboli.

Pharmacodynamics

Once inside the cells, fatty acids are used as energy or resynthesized into triglycerides and stored. For use as energy, triglycerides are transported into the mitochondria by carnitine palmitoyltransferase, where they undergo β oxidation sequentially releasing acetylcoenzyme A (acetyl-CoA) as the fatty acid chain is reduced in length. These acetyl-CoA molecules enter the Krebs cycle, where they ultimately generate adenosine triphosphate (ATP) (Figs. 13–3 and 13–8). Although glucose, lactate, and fatty acid metabolism may ultimately lead to the production of acetyl-CoA, fatty acid metabolism produces the largest amount of energy. For example, one mole of glucose produces 38 ATP, while one mole of stearic acid produces 146 ATPs⁹⁷; the metabolism of longer fatty acid chains may produce more ATP.

ROLE IN LOCAL ANESTHETIC TOXICITY

IFE was first studied as an antidote to bupivacaine toxicity. In a rodent model, pretreatment with IFE (10%–30%) followed by a continuous infusion of bupivacaine (10 mg/kg/min) increased the dose of bupivacaine needed to induce asystole.⁹⁶ In the second part of this study, bupivacaine was infused into rodents until the development of cardiac arrest. Rodents were resuscitated with IFE (30% IFE, 7.5 mL/kg bolus, then 3 mL/kg/min for 2 minutes) or an equivalent volume of saline. Animals were more successfully resuscitated with IFE from larger doses of bupivacaine than when treated with saline. The LD₅₀ for saline resuscitation was 12.5 mg/kg, which increased to 18.5 mg/kg with IFE resuscitation. In a larger animal model, canines were administered bupivacaine until cardiac arrest and then resuscitated with IFE (20% IFE, 4 mL/kg bolus, then 0.5 mL/kg/min for 10 minutes) or saline. IFE resulted in a dramatic survival benefit—all animals survived following IFE versus none in the control arm.⁸⁹ In rodent models, IFE was superior to epinephrine, vasopressin, and the combination in bupivacaine toxicity.^{14,93} These findings were not reproduced in several swine models in which epinephrine was superior to IFE and epinephrine alone or epinephrine plus IFE was superior to vasopressin alone or vasopressin plus IFE in bupivacaine toxicity.³² IFE was not effective in reversing local anesthetic toxicity and had minimal effect on bupivacaine and mepivacaine distribution.⁷¹ It is worth noting, however, that pH was not recorded in this study and the lipid solubility of bupivacaine is lower as pH decreases. This may explain the inability of IFE to change the distribution of the local anesthetics. Additionally, the swine model may not be appropriate to evaluate lipid resuscitation therapy. Swine develop complement activation-related pseudoallergy (CARPA), an acute hypersensitivity reaction to liposomes. CARPA is characterized by mottling, hypoxia, and cardiovascular instability, which might compromise IFE resuscitation. This may explain the incongruous effect of IFE in these swine models and hypotension when IFE is administered in some swine models.^{30,90}

Based on the experimental evidence in bupivacaine toxicity, IFE was successfully used in several reported human cases of cardiovascular collapse from local anesthetic overdose. The first human case occurred following the inadvertent intravenous administration of bupivacaine and mepivacaine during an interscalene block.⁶³ The patient developed cardiac arrest and was treated with cardiopulmonary resuscitation (CPR) and advanced cardiac life support (ACLS) for 20 minutes, but only had return of spontaneous circulation following administration of the first dose of IFE (100 mL of 20% IFE followed by 0.5 mL/kg/min for 2 hours). The second successfully treated case occurred when a patient developed asystole after inadvertent intravenous administration of ropivacaine during an axillary plexus block.⁴⁵ The patient received CPR and ACLS and had return of spontaneous circulation 10 minutes after IFE administration (100 mL of 20% or 2 mL/kg followed by an infusion at 10 mL/min for an additional dose of 100 mL). A comparable example was a 60 year-old man with diabetes, coronary artery disease, and end-stage kidney failure who became unresponsive and developed ventricular fibrillation and torsade de pointes after administration of mepivacaine and bupivacaine for a supraclavicular brachial plexus block. He received CPR and ACLS for 10 minutes and then was treated with IFE (250 mL of 20% over 30 minutes). His pulse and blood pressure returned 11 minutes later.⁸⁶

In addition to its use during resuscitation, IFE has been used to treat milder symptoms of local anesthetic toxicity such as CNS symptoms and dysrhythmias without loss of pulse. A patient developed agitation, dizziness, unresponsiveness, and atrial premature contractions and bigeminy after administration of mepivacaine and prilocaine for a brachial plexus block. IFE treatment alone (1 mL/kg of 20%, repeated at 3 minutes for a total of 100 mL, followed by a continuous infusion of 0.25 mL/kg/minutes or 14 mL/min) rapidly resolved his dysrhythmia and restored consciousness.⁴⁷ A 75 year-old woman developed a seizure, wide complex dysrhythmia, and hypotension following levobupivacaine administration for a lumbar plexus block. She was treated with propofol, metaraminol, and IFE (20%, 100 mL over 5 minutes). During IFE infusion, the QRS narrowed and blood pressure and electrocardiogram normalized within 10 minutes.²⁰ A 13 year-old patient developed ventricular tachycardia at 150 beats/min after receiving lidocaine with epinephrine and ropivacaine for a lumbar plexus block. Treatment with IFE alone (150 mL or 3 mL/kg of 20% IFE over 3 minutes) restored a normal QRS complex within 2 minutes. Subsequent reviews of published human case reports document 19 case reports using IFE for resuscitation for local anesthetic toxicity, and the majority report improvement.^{11,35,62,64,85}

ROLE IN NON-LOCAL ANESTHETIC TOXICITY

IFE was first studied as an antidote to bupivacaine toxicity and then evaluated for calcium channel blocker, cyclic antidepressant, β -adrenergic antagonist, organic phosphorus compounds, amiodarone, cocaine, and thiopental toxicity. In a controlled rodent study, a continuous infusion of verapamil followed by treatment with 12.4 mL/kg bolus of 20% IFE resulted in an increase in heart rate and survival compared with control.⁷⁸ In a larger animal model of verapamil toxicity in which animals also received calcium and atropine, 7 mL/kg of 20% IFE over 30 minutes resulted in improved blood pressure and survival.⁴

In an experimental model of clomipramine toxicity,²⁸ rabbits were given clomipramine until mean arterial pressure decreased to 50% of baseline. They were then treated with sodium bicarbonate (3 mL/kg of 8.4%), IFE (12 mL/kg of 20%), or sodium chloride (12 mL/kg of 0.9%). IFE resulted in an increase in mean arterial pressure greater than sodium chloride and sodium bicarbonate. In a second part of this study, clomipramine was administered until cardiovascular collapse, which was followed by resuscitation with sodium bicarbonate (2 mL/kg of 8.4%) or IFE (8 mL/kg of 20%) delivered over 2 minutes. With four animals in each study arm, IFE markedly improved survival compared to sodium bicarbonate (100% versus 0%).

In a rodent model using a constant infusion of propranolol, IFE decreased QRS prolongation, but the study was underpowered to detect an effect on heart rate or survival.¹¹ In another rodent and rabbit model of propranolol toxicity, IFE resulted in an increase in blood pressure.⁶ In contrast, in a metoprolol model, IFE was not effective in reversing hypotension and bradycardia, which was attributed to the lower lipid solubility of metoprolol compared to propranolol.⁷

In an oral organic phosphorus compound toxicity model, IFE administered 20 minutes after parathion exposure prolonged the time to apnea compared to saline and administering IFE 5 minutes after exposure.¹⁶

In a rodent model of thiopental anesthesia, IFE administered postanesthesia resulted in an increase in respiratory rate compared to saline.⁶⁶ Similarly, in a model of thiopental anesthesia, pretreatment with IFE decreased anesthesia time as measured by a return in righting reflex in rodents.¹⁰ However, in one animal model of thiopental anesthesia, IFE increased the CNS effects.³⁶

In a rodent model of cocaine toxicity, IFE was administered as pretreatment for cocaine toxicity. Pretreatment with IFE blunted the hypotensive effect of cocaine and increased survival.⁸

Based on the experimental evidence, IFE use was expanded to non-local anesthetic toxicity. IFE was successfully used to resuscitate a 17-year-old patient with prolonged cardiovascular collapse after bupropion and lamotrigine overdose. In this case, the patient had experienced seizures and underwent ACLS and CPR for 70 minutes, with return of spontaneous circulation after IFE administration (a bolus of 100 mL of 20%).⁷²

In the largest case series to date of IFE in non-local anesthetic toxicity, using the Toxicology Investigators' Consortium (ToxIC) database, investigators report nine cases with drug-induced cardiovascular collapse treated with IFE in addition to standard resuscitative measures. Five of the nine patients treated with IFE survived, although several adverse effects were probably or possible as a result of the IFE such as acute respiratory distress syndrome (ARDS), acute kidney injury, and deep vein thrombosis.²¹ Subsequent reviews and published human case reports document more than 55 case reports of IFE for resuscitation in non-local anesthetic toxicity. Improvement is reported for amlodipine, diltiazem, verapamil, atenolol, nebivolol, propranolol, carvedilol, flecainide, haloperidol, amitriptyline, dosulepin, doxepin, imipramine, quetiapine, venlafaxine, carbamazepine, lamotrigine, phenobarbital, diphenhydramine, bupropion, hydroxychloroquine, cocaine, and bromadiolone.^{12,12,64,85} Despite these successful reports, data are limited by reporting biases, therapeutic effects resulting from additional coadministered therapies, and coingestant xenobiotic toxicity. Current case report data only suggest a possible benefit of IFE tricyclic antidepressant bupropion, lipophilic β -adrenergic antagonist, and calcium channel blocker toxicity.¹²

ADVERSE EFFECTS AND SAFETY ISSUES

The adverse effects attributed to IFE administration are infrequent and limited primarily to pulmonary toxicity and pancreatitis.^{12,91} The doses and short durations of administration used in most patients result in full recovery without any significant adverse effects.^{12,35,64,85} Based on case reports, a dose of 1.5 mL/kg bolus of 20% IFE followed by 0.25 mL/kg/min or 15 mL/kg/h to infuse for 30 to 60 minutes appears to be safe in xenobiotic-induced cardiac arrest and severe toxicity.

Because of the limited number of case reports, toxicity from IFE remains a concern. Pulmonary toxicity is reported when IFE is used as a source of parenteral nutrition. In patients with ARDS, 500 mL of 20% IFE administered over 8 hours resulted in increased pulmonary artery pressures, pulmonary shunting, pulmonary vascular resistance, and decreased partial pressures of oxygen in the alveoli/fraction of inspired oxygen (P_{AO_2}/FIO_2).⁸³ Similar results were found in patients with ARDS administered 500 mL of 10% IFE over 4 hours, resulting in an increase in pulmonary shunting and a decrease in the

fraction of PAO_2/FIO_2 .³⁴ The pulmonary effect of IFE in ARDS may be related to infusion rate. In patients with ARDS, 500 mL of 20% IFE infused over 5 hours resulted in an increase in pulmonary pressures, while a slower infusion over 10 hours left pulmonary pressures unchanged.⁵⁰ There are conflicting results of the effects of IFE in patients without ARDS. In septic and nonseptic patients without ARDS, 500 mL of 20% IFE administered over 10 hours resulted in an increase in pulmonary artery pressures and pulmonary shunting.⁸² In patients with chronic obstructive pulmonary disease and pneumonia, 500 mL of 10% IFE administered over 4 hours had no pulmonary effects, and in a group of healthy postoperative patients this dose actually decreased pulmonary shunting and increased PAO_2/FIO_2 ratio.³⁴

In these studies, when pulmonary effects occurred, they were mild and resolved after the IFE infusion was stopped or within 3 to 4 hours. Larger doses may result in clinically significant toxicity and more prolonged effects. However, studies using fat emulsions with medium-chain triglycerides have shown less pulmonary toxicity.^{18,73}

IFE may cause pulmonary toxicity by at least two mechanisms. IFE may occlude the pulmonary vasculature with microfat emboli. Macrophages containing lipid droplets can be demonstrated in the bronchioalveolar lavage fluid of ARDS patients treated with IFE.⁴² Experimental evidence also suggests that a substantial amount of the high concentrations of linoleic acid in IFE is converted to arachidonic acid and then into vasoactive prostaglandins. Indomethacin, an inhibitor of prostaglandin synthesis, prevented any pulmonary vascular effect caused by IFE in a sheep model.⁵³

Adverse effects resulting from IFE use in resuscitation from xenobiotic toxicity are uncommon. Investigators using the ToxIC database report that three of the five patients successfully resuscitated with IFE developed ARDS that was probably attributed to IFE.³⁵ It is difficult to attribute the etiology solely to IFE as these patients were predisposed to ARDS due to xenobiotic toxicity, hypotension, and potential aspiration.

Elevated triglycerides and pancreatitis is reported when IFE is used for parenteral nutrition. The precise mechanism of IFE-induced pancreatitis is unknown but may be the result of the large concentration of triglycerides forming large lipid droplets that obstruct the small vessels of the pancreas, leading to ischemia. Lipase then degrades the triglycerides, releasing cytotoxic free fatty acids.

Hyperamylasemia and pancreatitis were reported in two cases of IFE use in treatment of xenobiotic toxicity. Following successful resuscitation with IFE from bupivacaine-induced cardiac arrest, an elevated amylase concentration without associated elevated lipase or associated symptoms was reported.⁸¹ Elevated lipase concentrations were reported after administering IFE to a 13 year-old girl who developed delayed seizures and cardiac arrest following an amitriptyline ingestion. Lipase concentrations peaked at 1849 U/L 5 days after IFE and was associated with elevated triglycerides and abdominal pain.⁴²

Large doses and/or rapid infusions of IFE have the potential to induce a fat overload syndrome. Fat overload syndrome is characterized by hyperlipemia, fever, fat infiltration, hepatomegaly, jaundice, splenomegaly, anemia, leukopenia, thrombocytopenia, coagulation disturbances, seizures, and coma. Multiple end-organ dysfunction is attributed to inadequate clearance of lipids and sludging in the lungs, brain, kidney, retina, and liver.^{15,17,25,31,39,42,68,70,77} Because of the rapid redistribution of most local anesthetics, prolonged IFE infusion should not be required ([Chap. 67](#)). However, many other lipid-soluble xenobiotics have a long duration of toxicity, and prolonged and repeated IFE infusions may be recommended, predisposing to fat overload syndrome.

Particularly when administered early in the clinical course of an overdose, IFE has the potential to increase gastrointestinal absorption or facilitate distribution of lipid-soluble xenobiotics, resulting in increased toxicity. Although this currently remains a theoretical concern, some animal models suggest certain xenobiotics could partition into IFE and contribute to additional toxicity. In an orogastric model of amitriptyline overdose, IFE increased amitriptyline concentrations and resultant toxicity.⁶¹ In a model of thiopental anesthesia, IFE increased sedation, possibly by increasing concentrations of thiopental in the serum, permitting extended time for distribution into the CNS.³⁶ IFE also has the potential to interact with other essential antidotes. If an antidote is lipid soluble, it may be incorporated by the IFE and result in decreased effectiveness. Both thiopental and lidocaine are highly lipid soluble, and IFE may decrease their effectiveness. In a rodent model, pretreatment with IFE delayed the peak effect and prolonged the duration of effect of epinephrine on mean arterial pressure.⁹ Clinical data are absent. IFE has been used with several medications during resuscitation from bupivacaine toxicity, including epinephrine, atropine, amiodarone, vasopressin, sodium bicarbonate, magnesium sulfate, calcium chloride, naloxone, and metaraminol.^{12,36,64,85}

The addition of IFE to high-dose insulin-euglycemia (HIE) was evaluated in a model of severe verapamil toxicity, and there was no improvement in hemodynamics, metabolic parameters, or survival.⁵ Therefore, while other resuscitative xenobiotics should be used as indicated, there is no evidence yet to support or refute the simultaneous use of IFE and HIE therapy.

Hyperlipidemia after using IFE may interfere with laboratory studies and make them uninterpretable.⁴² This interference may last for several hours and may depend on the type of laboratory system used. IFE may alter analytical test results and result in erroneous measurement, no significant effect, or the inability to perform a laboratory test. In vitro testing of IFE demonstrated that colorimetric methods were more prone to the effects of IFE than potentiometric methods. In the setting of

IFE, glucose measurement by colorimetric method did not accurately report hypoglycemia. For example, a glucose concentration of 2.7 mmol/L (48.6 mg/dL) may be falsely reported as 12.4 mmol/L (223.2 mg/dL). Centrifugation at 140,000 g for 10 minutes minimized most interference. Troponin-I, sodium, potassium, chloride, calcium, bicarbonate, or urea assays had the least interference. Albumin and magnesium assays demonstrated significant interference. Amylase, lipase, phosphate, creatinine, total protein, alanine aminotransferase, creatine kinase, and bilirubin became unmeasurable.²² The effect of IFE on toxicology testing is unknown. Ideally, analytic testing should be performed prior to the IFE administration.

Based on a risk benefit analysis, relative contraindication to IFE is egg or soybean allergy, disorders of fat metabolism, and liver disease. Consideration should also be made in patients with myocardial ischemia and infarction. In animal models, IFE increased dysrhythmias and impaired cardiac pump performance when administered during ischemia^{40,74} but was of benefit when administered after the resolution of ischemia. In an ischemic myocardial cell, fatty acid metabolism is thought to result in lipid peroxidation and free radical production, which increases dysrhythmias and impairs myocardial performance.⁷¹

Pregnancy and Lactation

IFE is a pregnancy category C pharmaceutical. It is not known whether IFE can cause fetal harm when administered to gravid patients. Potentially, large doses can result in elevated triglyceride concentrations, and lipid globules may potentially occlude placental vasculature. Risk of potential toxicity should be weighed against potential benefit to the pregnant woman and fetus. There is no reported risk of IFE on the nursing infant.

DOSING AND ADMINISTRATION

Although the optimal dosing regimen for human poisonings remains undefined, several animal models of high-dose IFE have been performed. In both rodent and canine models of verapamil toxicity, 12.4 and 7 mL/kg boluses of 20% IFE were given,^{5,78} and in a rabbit model of clomipramine, 12 mL/kg of 20% IFE was used.⁷⁹ These animal models used large doses of xenobiotic and were designed to produce a rapid onset of toxicity; it is difficult to extrapolate to typical human cases. In a rodent model, the LD₅₀ of IFE is 67 mL/kg, which is much higher than the current recommended clinical doses.

Additionally, only microscopic abnormalities were observed in the lung and liver at doses of 60 and 80 mL/kg, which improved over 24 hours. Higher doses of IFE also are more effective than lower doses. In a model of verapamil toxicity, higher doses up to a maximum of 18.6 mL/kg of 20% IFE were more effective in improving blood pressure, acidemia, and survival than lower doses. Higher doses improved hemodynamic parameters transiently, but may have also resulted in overall decreased survival times.⁶⁰

The dose of IFE administered depends on the implicated xenobiotic and the patient's clinical condition. Dosing is best defined for local anesthetic toxicity, specifically bupivacaine, with generalization of this dosing regimen to poisoning by other local anesthetics and other xenobiotics. The American Society of Regional Anesthesia and Pain Management, the Association of Anesthetists of Great Britain and Ireland, and the American Heart Association^{23,57} have similar guidelines and recommendation on the use of IFE in local anesthetic toxicity. Lipid treatment is recommended for clinically severe cardiovascular toxicity or rapid progression of toxicity.

The recommended dose of 20% IFE is 1.5 mL/kg bolus followed by 0.25 mL/kg/min or 15 mL/kg/h to run for 30 to 60 minutes.^{23,57} The bolus may be repeated several times for persistent dysrhythmias, and the infusion rate can be increased if blood pressure decreases. For local anesthetic poisoning, earlier recommendations limited use of IFE only to situations following the failure of standard resuscitative measures. As a result of the experimental evidence and many successful case reports, some authors recommend adding IFE at the first signs of local anesthetic toxicity or, in the setting of cardiovascular collapse, to use IFE concomitantly with CPR and ACLS and to avoid high doses of epinephrine.⁹² We recommend that rapid progression of local anesthetic toxicity affecting the CNS (agitation, confusion, seizures) or cardiovascular system (hypertension, tachycardia, ventricular dysrhythmias, hypotension, conduction blocks) should be treated with IFE. In the setting of cardiovascular collapse, IFE can be used with CPR and standard ACLS. IFE should be stored for easy and rapid access in operating rooms or in areas where local anesthetics are frequently used.⁶⁵ Generalization of this practice to other xenobiotics is not currently studied or recommended.

Experimental evidence indicates that IFE may be potentially beneficial in verapamil,^{4,60,79} clomipramine,^{28,29} propranolol,^{6,26} amiodarone,¹⁷ and cocaine⁸ toxicity, and this may be extrapolated to other lipid-soluble calcium channel blockers, cyclic antidepressants, or lipophilic β -adrenergic antagonists. These xenobiotics will usually demonstrate continued absorption, long duration of toxicity, severe hypotension, and either dysrhythmias or bradycardia over several hours or days. The precise indications and dose of IFE for these situations has not been studied, and it is not known if boluses or infusion are more effective. The reasonable safe total dose is also unknown but would depend upon the degree of toxicity and response to previous doses of IFE. Based on the current data available from animal models and clinical case reports, the American College of Medical Toxicology published interim guidance on the use of IFE in lipophilic xenobiotic

toxicity.¹ Published guidance states that IFE is a reasonable consideration in serious hemodynamic, or other, instability from a xenobiotic with a high degree of lipid solubility, even if the patient is not in cardiac arrest. However, IFE can be considered for patients with hemodynamic instability refractory to standard resuscitation measures. No standards for use were set, and the dosing recommended was similar to the dose recommended for local anesthetic toxicity. We recommend that IFE be used in the setting of severe toxicity (prolonged cardiovascular instability such as hypotension, severe bradycardia or dysrhythmias or seizures) resulting from a lipid soluble xenobiotic despite maximal treatment with standard resuscitation measures. When used, we recommend a bolus dose of 1.5 mL/kg of 20% IFE, which should be followed by an infusion for 30 to 60 minutes of 0.25 mL/kg/min or 15 mL/kg/h. Repeat boluses of IFE can be administered for persistent severe symptoms.

Propofol is formulated as a 10% lipid emulsion, but it is not recommended for use in lipid rescue because of the adverse effect of the propofol from the dose needed to achieve lipid rescue.⁸⁸ A 1.5 mL/kg bolus of 20% IFE equates to 3 mL/kg of the 10% lipid emulsion in the propofol solution. A normal dose of propofol (1%) for general anesthesia is 2.5 mg/kg or 0.25 mL/kg.⁶⁸ If propofol is used as a lipid rescue agent, it would deliver a bolus of 12 times the recommended dose of propofol. This would exacerbate any drug-induced hypotension and bradycardia.

FORMULATION AND ACQUISITION

IFE is available in 5%, 10%, 20%, and 30% solutions. The 20% solution is recommended and used most often. The 30% solution is a pharmacy bulk admixture and is used to prepare dilute concentrations. The 30% solution should be diluted before administration and has not been used clinically for xenobiotic toxicity.

There are some current shortages reported for IFE. There are no recommended alternative agents, but if available, dose adjustment can be made to the lower and higher concentrations, and medium chain preparations can be used as a substitute.

SUMMARY

- IFE is recommended for the treatment of local anesthetic systemic toxicity, particularly in the case of rapidly progressive toxicity or cardiac arrest.
- In local anesthetic systemic toxicity, IFE can be used with standard resuscitation medications and should be stored where local anesthetics are administered.
- IFE use for other xenobiotics is unclear at this time, although animal data and some human case reports support its use for several lipid-soluble xenobiotics such as verapamil, clomipramine, and some lipophilic β -adrenergic antagonists.
- IFE use for other xenobiotics should be considered when severe toxicity resulting from a lipid-soluble xenobiotic persists despite maximal treatment with standard resuscitation measures.
- For both local anesthetic and non-local anesthetic toxicity, a bolus dose of 1.5 mL/kg of 20% IFE should be followed by an infusion for 30 to 60 minutes of 0.25 mL/kg/min or 15 mL/kg/h. Repeat boluses of IFE can be administered for persistent severe signs and symptoms.

68 INHALATIONAL ANESTHETICS

Brian Kaufman

HISTORY AND EPIDEMIOLOGY

The earliest description of the use of an inhalational anesthetic was made by Paracelsus, a Swiss physician and alchemist who prepared a mixture of diethyl ether, alcohol, and water called sweet oil of vitriol. He described the administration of this preparation to hens that fell into what appeared to be a deep sleep from which they recovered unharmed. In 1735, Wilhelm Froben gave this substance its modern name of “ether.” Ether was used topically, particularly via the intranasal route, as a treatment of headache, nervous diseases, and fits.

Modern anesthetic practice often is stated to have begun in 1846 at the Massachusetts General Hospital, when the dentist William Morton gave the first public demonstration of the ability of inhaled ether vapor to alleviate the pain of surgery. Oliver Wendell Holmes chose the Greek-related noun anesthesia (without feeling) to characterize the process.

Observations on circulatory and respiratory physiology eventually led to an understanding of the effects of inhalation gases and vapors. In the last decade of the 18th century, centers for the pneumatic treatment of disease were established in Birmingham and Bristol, England. Experiments with ether that was inhaled via a funnel and with nitrous oxide were conducted at these institutions. After Humphry Davy described his own pleasurable and exhilarating experience when he inhaled the “laughing” gas, many of his colleagues and friends inhaled nitrous oxide to experience its inebriating effects. Davy also described how inhalation of nitrous oxide relieved headache and the pain of an erupting molar tooth. Although Davy recognized the analgesic properties of nitrous oxide and its possible application for surgery, he failed to pursue the idea.

The public soon took up the use of nitrous oxide in the form of nitrous oxide frolics. Audience members at itinerant medicine shows volunteered to experience the exhilarating effects of nitrous oxide inhalation. At one such show in 1844 in Hartford, Connecticut, a man under the influence of nitrous oxide injured his leg but felt no pain. Dr. Horace Wells, a dentist in the audience that day, inhaled nitrous oxide the following day and had his partner painlessly remove a troublesome tooth. A subsequent public demonstration of the use of nitrous oxide for dental extraction was partly unsuccessful, leaving his colleagues doubtful regarding its efficacy and safety and thereby impeding its general acceptance as a surgical anesthetic.

In Great Britain in 1847, James Simpson, an obstetrician, first used ether to relieve the pain of labor. He subsequently adopted chloroform for this purpose because of its more pleasant odor and more rapid induction and emergence. The clergy and other physicians opposed the concept of relieving pain during childbirth, but the method ultimately was accepted after Queen Victoria gave birth to Prince Leopold with chloroform given by John Snow.

Over the next century, several volatile anesthetics were introduced, including ethyl chloride in 1848, divinyl ether in 1933, trichloroethylene in 1934, and ethyl vinyl ether in 1947. All had significant safety problems associated with their use, including combustibility and direct organ toxicity.

Advances in fluorine chemistry led to the cost-effective incorporation of fluorine into molecules used in the development of modern anesthetics. Fluroxene was the first of the new fluorinated anesthetics to be widely used clinically. However, this anesthetic was flammable and hepatotoxic. It was largely replaced by the nonflammable halothane, which was synthesized in 1951 and introduced into clinical practice in 1956. Methoxyflurane was evaluated in humans in 1960 but is no longer used because of nephrotoxicity ([Chap. 19](#)) and hepatotoxicity. Other halogenated hydrocarbons with improved clinical properties have been introduced, including enflurane, isoflurane, desflurane, and sevoflurane ([Fig. 68–1](#)). The inert gas xenon may be a useful anesthetic and is both cardio- and neuroprotective in experimental studies.⁴³ The clinical use of xenon is limited both by its cost and difficulty to manufacture. Although xenon is environmentally friendly compared with presently used anesthetic gases, its toxicity is relatively unknown but is believed to be minimal.

FIGURE 68–1. The inhalational anesthetics.

PHARMACOLOGY

Inhalational anesthetics remain the most popular anesthetics used for maintenance of anesthesia primarily because they are easily and safely administered by modern anesthesia machines and are rapidly titratable to effect. Inhalational anesthetics used in current clinical practice include nitrous oxide, halothane, isoflurane, sevoflurane, and desflurane.

Because a wide range of chemically distinct xenobiotics can produce anesthesia, a unique receptor for the inhaled anesthetics is improbable. More likely, the volatile anesthetics cause general anesthesia by modulating synaptic function from within cell membranes. Anesthetics interact with many proteins. The most likely, but not yet proven, targets for the inhalational anesthetics are the ion channels that control ion flow across the cytoplasmic membrane.¹¹ An in-depth discussion is beyond the scope of this chapter, but several concepts are important to consider. First, more than 20 different ion channels have been identified, each controlling various anion and cation flows. The results of these ion channel effects include release of inhibitory neurotransmitters and inhibition of excitatory neurotransmitters. In fact, each anesthetic type has variable actions. The receptor for γ -aminobutyric acid type A (GABA_A) is the best studied and plays an important role because GABA_A is an inhibitory neurotransmitter. The interaction of all of these receptor effects produces the condition we refer to as general anesthesia. Many of the adverse effects of the inhalational anesthetics result directly from ion channel effects in nonneural tissue, primarily cardiac cell membranes.

Reversible changes in neurologic function cause loss of perception and reaction to pain, unawareness of immediate events, and loss of memory of those events. The common pharmacologic mechanisms for general anesthesia include the physical–chemical behavior of volatile hydrocarbons within the hydrophobic regions of biologic membrane lipids and proteins.

The potency of the various inhaled anesthetics correlates with their physicochemical properties. The dominant theories of the molecular mechanisms by which volatile anesthetics affect membrane function are based on the lipid solubility of the xenobiotics and experimental demonstration of pressure reversal of anesthesia. Anesthetic potency correlates directly with the relative lipid solubility of each xenobiotic, suggesting that the primary molecular actions of anesthetics occur in the lipid portion of cell membranes. This mechanism is known as the Meyer-Overton lipid solubility theory. Potential membrane regions for anesthetic action include the hydrophobic areas of proteins and protein–lipid interface regions, as well as the phospholipid matrix. High pressures (100–200 atm) can reverse the anesthetic effects of several xenobiotics, suggesting that anesthesia results from increasing membrane volume at normal atmospheric pressure, an effect known as the volume expansion theory.

PHARMACOKINETICS

Because the inhaled anesthetics enter the body through the lungs, the factors that influence their absorption by blood and distribution to other tissues, particularly the brain, include the solubility of the xenobiotic in blood, blood flow through the lungs, blood flow distribution to the various organs, solubility of the anesthetic in tissue, and the mass of the tissue. The goal of inhalation anesthesia is to develop and maintain a satisfactory partial pressure of anesthetic in the brain, the primary site of action.

The pharmacokinetics of anesthetics can be linked to their pharmacodynamics by considering anesthetic potency. The linkage exists because anesthesia strives to achieve and maintain a desired alveolar concentration. For the inhaled anesthetics, potency is commonly designated by the minimum alveolar concentration (MAC) of the anesthetic. MAC is the alveolar concentration at 1 atm that prevents movement in 50% of subjects in response to a painful stimulus. MAC is used when comparing the effects of equipotent doses of anesthetics on various organ functions.

NITROUS OXIDE

Nitrous oxide (N_2O) is the most commonly used inhalational anesthetic in the world, but its safety is debated.²⁷ In 2008, the toxicity of nitrous oxide was exhaustively reviewed both from its chemical perspective and its clinical activity, and the authors concluded that a ban on its use is not required.⁴⁴ Its advantages include a mild odor, absence of airway irritation, rapid induction and emergence, potent analgesia, and minimal respiratory and circulatory effects. When administered in a modern operating room (OR) using current standards of monitoring to prevent unintentional hypoxia, nitrous oxide is a remarkably safe xenobiotic. Unfortunately, nitrous oxide also has a potential for abuse, particularly among hospital and dental personnel.²⁶ Death and permanent brain injury are reported but do not generally result from direct toxic effects; instead, they are secondary to hypoxia as a result of simple asphyxiation¹⁵ (Chap. 124).

Nitrous oxide is also used as a food additive to generate foam, a property exploited to produce whipped cream. Sold in supermarkets as “bulbs,” death has occurred secondary to asphyxiation, when a homemade mouthpiece “whippets” failed to separate from the user after unconsciousness occurred during use.⁴²

Death also has occurred when patients received commercially prepared nitrous oxide from tanks contaminated with impurities such as nitric oxide or nitrogen dioxide. Pulmonary toxicity resulting from similar contaminants has been reported after illicit preparation of nitrous oxide from the combustion of ammonium nitrate fertilizer.³³

Injury may result from the physical properties of this anesthetic. Nitrous oxide is 35 times more soluble in blood than is nitrogen. When nitrous oxide is inhaled, any compliant air-containing space, such as the bowel, increases in size; noncompliant spaces, such as the eustachian tubes, exhibit an increase in pressure. These effects occur because nitrous oxide diffuses along the concentration gradient from the blood into a closed space much more rapidly than nitrogen can be transferred in the opposite direction. Clinical consequences include rapid progression of a pneumothorax to a tension pneumothorax, tympanic membrane rupture with hearing loss, bowel distension, and tracheal or laryngeal trauma caused by increased endotracheal cuff pressure resulting from replacement of air by a larger volume of nitrous oxide. Nitrous oxide may be particularly dangerous in patients who have suffered air emboli, and its use should be immediately discontinued upon recognition of these events. When intracranial or neuraxial air is injected during placement of an epidural catheter, it also can theoretically expand upon subsequent exposure to nitrous oxide.

Hematologic Effects

Bone marrow suppression was first recognized as a complication of long-term nitrous oxide exposure in the 1950s, when the gas was used to sedate intubated patients who had severe tetanus.²⁵ Leukopenia with hypoplastic bone marrow and megaloblastic erythropoiesis typically developed 3 to 5 days after initial exposure and was followed by thrombocytopenia. Recovery usually occurred within 4 days after the anesthetic was discontinued. Healthy patients undergoing routine surgical procedures demonstrate mild megaloblastic bone marrow changes within 12 hours of exposure to 50% nitrous oxide and marked changes within 24 hours.⁴⁰ Critically ill patients may be more sensitive to the effects of nitrous oxide on the bone marrow, with megaloblastic changes described after only one hour of exposure, but changes are unlikely in individuals with less than 6 hours of exposure in the absence of preexistent folate or cobalamin deficiencies.³

The hematologic effects of exposure to nitrous oxide strongly resemble the biochemical characteristics of pernicious anemia.^{2,38,39} Vitamin B_{12} , or cyanocobalamin, is a bound coenzyme of cytoplasmic methionine synthase. The cobalt moiety in the enzyme functions as a methyl carrier in its transfer from 5-methyltetrahydrofolate to homocysteine to form methionine (Fig. 68–2). Nitrous oxide oxidizes the cobalt ion, converting vitamin B_{12} from the active monovalent form (Co^+) to the inactive divalent form (Co^{2+}), which irreversibly inhibits methionine synthase.³⁸ The metabolic consequences of this inhibition are significant because methionine and tetrahydrofolate are required for both DNA synthesis and myelin production. This interference is responsible for the development of bone marrow depression and polyneuropathy resembling the characteristic findings that occur in pernicious anemia.³⁹

FIGURE 68–2. Hematologic effects of exposure to nitrous oxide (NO) resemble those characteristic of pernicious anemia and are related to oxidation and inactivation of vitamin B₁₂. The irreversible blockade of methionine synthase impairs DNA synthesis and myelin production.

Neurologic Effects

Disabling polyneuropathy in health care workers who habitually abused nitrous oxide was first described in 1978.²⁶ This neurologic disorder improved slowly when the patients abstained from further nitrous oxide abuse. This neuropathy is clinically indistinguishable from subacute combined degeneration of the spinal cord associated with pernicious anemia.⁴⁵ The syndrome of nitrous oxide neuropathy is characterized by sensorimotor polyneuropathy, often combined with signs of posterior and lateral spinal cord involvement. Signs and symptoms include numbness and paresthesias in the extremities, weakness, and truncal ataxia. Neurologic changes usually develop only after several months of frequent exposure to nitrous oxide, although neurologic manifestations may develop within days of use in patients with subclinical cyanocobalamin deficiency. Those at risk include individuals who chronically abuse the gas and those who are occupationally exposed for prolonged periods to environments contaminated with high concentrations of nitrous oxide.⁵ Animal studies demonstrate that methionine synthase is inactivated by exposure to greater than 1000 parts per million (ppm) of nitrous oxide. This scenario is highly unlikely in modern ORs, where inhalational anesthetics are scavenged, but it may occur in poorly ventilated dental offices. This problem probably is markedly underdiagnosed because the neurologic changes that occur in mild cases mimic other more common neurologic conditions.⁹

Immunologic Effects

Recently, concern has been raised regarding detrimental effects of nitrous oxide on immune function. Nitrous oxide is associated with varied effects on immune function with evidence of decreased proliferation of human peripheral blood mononuclear cells and decreased neutrophil chemotaxis. A large multicenter controlled trial (ENIGMA) evaluated 2050 patients undergoing major surgery, comparing a group receiving 80% oxygen/20% nitrogen with those receiving 70% nitrous oxide/30% oxygen.³⁵ On subgroup analysis, the group receiving nitrous oxide demonstrated significant increases in the incidence of wound infection, pneumonia, and atelectasis. Because the differences may be related to beneficial effects of high inspired oxygen concentrations rather than detrimental effects of nitrous oxide, follow-up studies (ENIGMA II) are being done to address these methodologic concerns.³⁶

Cardiovascular Effects

The use of nitrous oxide is associated with an increased risk of cardiovascular complications in the perioperative period. Serum homocysteine concentrations increase for days after operative exposure to nitrous oxide.³⁴ This occurs because conversion of homocysteine to methionine is methionine synthase dependent. Increased homocysteine concentrations are an independent risk factor for cardiac morbidity. In the ENIGMA trial, patients anesthetized with nitrous oxide had

significantly greater incidence of electrocardiographic abnormalities and cardiac enzyme elevations.³⁶ There was also a trend to a higher incidence of confirmed myocardial infarction in the nitrous oxide group as well as an increased long-term risk of myocardial infarction.²⁷

Treatment

General. Removal of the acutely affected person from the toxic environment should be the initial intervention. Individuals who have developed toxicity from occupational exposure or abuse of the gas should be educated about the relationship between their activities and their clinical findings.

Specific. Vitamin B₁₂ may help patients with a vitamin B₁₂ deficiency who develop megaloblastic anemia and neurologic dysfunction after brief exposure to nitrous oxide, but it is not beneficial in patients who have toxicity resulting from more chronic exposure. The reason for the ineffectiveness of vitamin B₁₂ in this situation is uncertain.

The bone marrow abnormalities associated with nitrous oxide toxicity may be reversed by administration of a single 30 mg intravenous (IV) dose of folinic acid (Antidotes in Depth: A10). Methionine has also been successfully used when vitamin B₁₂ treatment alone has failed to improve neurologic symptoms.⁴⁷

HALOGENATED HYDROCARBONS

The inhaled anesthetics were initially considered biochemically inert. Toxicity after administration was poorly explained, although it is now clear that the metabolites of the inhalational anesthetics are responsible for acute and chronic toxicities, which are predictable and dose related.

Halothane Hepatitis

Two distinct types of hepatotoxicity are associated with halothane use. The first is a mild dysfunction that develops in approximately 20% of exposed patients. Patients often are asymptomatic but exhibit modestly elevated serum aminotransferase concentrations within a few days of anesthetic exposure. Recovery is complete.²² In contrast, a life-threatening hepatitis occurs in approximately 1 in 10,000 exposed patients and produces fatal massive hepatic necrosis in 1 in 35,000 patients.⁴⁸ Because the histologic findings of massive hepatocellular necrosis are indistinguishable from many of the causes of viral hepatitis,⁵² differentiating halothane hepatitis from other causes of hepatitis in the postoperative period is difficult without definitive serologic studies. Jaundice, which is common after anesthesia and surgery, usually results from factors such as preexisting liver disease, blood transfusion, sepsis, or other causes of hepatitis. Thus, halothane hepatitis is a diagnosis of exclusion or inclusion based on the chemical history.

Several studies report an association between multiple exposures to halothane and subsequent development of hepatitis.^{37,51,56} In one study, 95% of cases of halothane hepatitis occurred after repeat exposures, 55% of which involved reexposure within 4 weeks.⁵⁶ Under these circumstances, hepatic dysfunction usually is more severe, and the latency before clinical presentation usually is shorter than when the syndrome develops after initial exposure to halothane.⁵¹

Obesity is a risk factor commonly implicated in halothane hepatotoxicity.^{1,53} Increased fat stores may act as a “reservoir” for halothane, with slow and prolonged release into the circulation and subsequent increase in production of potentially hepatotoxic metabolites.

Most cases of halothane hepatitis occur in middle-aged patients, with women having twice the risk.²² Genetic factors may play a role in some patients, as indicated by a report of this syndrome in three pairs of related Mexican women.²¹

Mechanism of Toxicity. Halothane is the most extensively metabolized inhalational anesthetic. Approximately 20% of the absorbed anesthetic undergoes oxidative metabolism, principally by CYP2E1 in the liver, to trifluoroacetic acid. Reduction to trifluorochloroethane and difluorochloroethylene is a minor route of halothane metabolism that requires the absence of oxygen and the presence of an electron donor (Fig. 68–3). These volatile metabolites are free radicals, which may directly produce acute hepatic toxicity by irreversibly binding to and destroying hepatocellular structures. Alternatively, by acting as haptens, they may trigger an immune-mediated hypersensitivity response.^{41,54} The high percentage of patients with halothane hepatitis who had recent reexposure is most consistent with the latter mechanism in which the first exposure primes the development of antibodies to a haptenized protein.²²

FIGURE 68–3. Reductive metabolism of halothane results in the formation of a reactive metabolite that may directly bind macromolecules and create neoantigens or undergo further metabolism to trifluorochloroethane and difluorochloroethylene. CYP = cytochrome P450.

The use of halothane for inhalational anesthesia has markedly decreased in North America with the widespread availability of newer, safer halogenated anesthetics. Halothane is still widely used in some countries because it is inexpensive and provides a smooth induction of anesthesia.

Isoflurane and desflurane are pungent gases that can be airway irritants. Isoflurane, desflurane, and sevoflurane all appear to have low hepatotoxic potential. An immune form of hepatitis has been reported with all anesthetics except sevoflurane. Cross-sensitivity may exist, such that prior exposure to one anesthetic triggers hepatotoxicity upon subsequent exposure to a different anesthetic.

Nephrotoxicity

The kidneys are the only other organ at risk for toxicity from modern inhalational anesthetics. Methoxyflurane is an anesthetic that was introduced in 1962. By 1966, it was linked to the development of vasopressin-resistant polyuric renal insufficiency (nephrogenic diabetes insipidus) in 16 of 94 patients receiving prolonged methoxyflurane anesthesia for abdominal surgery¹³ (Chap. 19). Polyuria was associated with a negative fluid balance, elevations of serum sodium and urea nitrogen concentrations, osmolality, and a fixed urinary osmolality approximating that of serum. Kidney abnormalities lasted from 10 to 20 days in most patients but persisted for more than one year in three patients. Subsequent studies demonstrated that kidney toxicity was caused by inorganic fluoride (F^-) released during biotransformation of methoxyflurane.⁵⁰ The risk of toxicity was highly correlated with both the total dose of methoxyflurane (concentration times duration) and the peak serum F^- concentration.¹² The nephrotoxic serum F^- concentration is 50 to 60 $\mu\text{mol/L}$.¹² The factors that enhance biotransformation such as obesity and enzyme induction also increase the risk of toxicity. Although the precise mechanism by which fluoride produces its toxic effect on the kidneys is not clear, one hypothesis is that fluoride inhibits adenylate cyclase, thereby interfering with the normal action of antidiuretic hormone on the distal convoluted tubules.

Although methoxyflurane is no longer used, lessons learned regarding its toxicity are applied when evaluating the nephrotoxic potential of other fluorinated anesthetics. Of the currently used anesthetics (halothane, isoflurane, desflurane, sevoflurane), only sevoflurane undergoes biotransformation by defluorination.

Approximately 5% of sevoflurane is metabolized. This process occasionally results in sufficient serum F^- concentrations to produce transient decreases in urine-concentrating ability.²⁴ However, clinically evident renal impairment almost never occurs with use of sevoflurane.¹⁸ In volunteer studies, exposure to sevoflurane that resulted in high serum fluoride concentrations did not result in any urine-concentrating defects. In patients with chronic kidney disease (CKD), the risk of postoperative kidney dysfunction is believed to be worse with exposure to inhalational anesthetics. However, studies demonstrate that deterioration of kidney function does not occur after exposure to desflurane and isoflurane,³¹ possibly because intrarenal fluoride concentrations are more important than serum fluoride concentrations in the development of nephrotoxicity.

Sevoflurane reacts with the alkali within carbon dioxide absorbers to produce several degradation products, including a vinyl ether called compound A ($\text{CF}_2\text{C}(\text{CF}_3)\text{OCH}_2\text{F}$). Compound A causes renal tubular necrosis in rats, especially at the corticomedullary junction.^{23,55} The extent of nephrotoxicity is determined by both the concentration of compound A and the duration of exposure. Compound A is also conjugated, and its breakdown products are nephrotoxic.

Technical Issues. Extensive clinical experience with several million patients who were exposed to sevoflurane and 4000 closely studied volunteers failed to demonstrate nephrotoxicity.³¹ Higher concentrations of compound A are generated during low-flow anesthesia, use of high concentrations of sevoflurane, and increased temperature conditions. A high fresh-gas flow rate dilutes the concentration of compound A. Concern that higher compound A concentrations are generated when a low fresh-gas flow rate (eg, <2 L/min) is used in a closed circuit led to the current sevoflurane package labeling, which warns against fresh-gas flow rates below 2 L/min in a circle absorber system.³⁰

Some controversy exists regarding the safety of low-flow sevoflurane anesthesia. Although there have been no clinical reports of sevoflurane-induced nephrotoxicity as measured by changes in blood urea nitrogen (BUN), serum creatinine, or creatinine clearance, clinical data demonstrate transient nephrotoxicity when more subtle measurements of glomerular and tubular function are used.^{16,18,20} For example, when young, healthy patients without underlying kidney disease were anesthetized with low-flow sevoflurane for a mean of 6.7 hours, transient but statistically significant increases in urinary glucose and protein excretion were documented without any changes in BUN, creatinine, or creatinine clearance.²⁰ The clinical significance of such transient abnormalities in kidney function is uncertain. Regardless, it seems prudent to avoid the practice of low-flow sevoflurane in patients with CKD until clinical data document safety. Newer carbon dioxide absorbents that are free of strong alkali are now available to decrease generation of compound A.

INHALATIONAL ANESTHETIC-RELATED CARBON MONOXIDE POISONING

Pharmacology

Desflurane and isoflurane contain a difluoromethoxy moiety that can be degraded to carbon monoxide (CO). This process occasionally results in patient exposure to toxic CO concentrations. CO production resulting from intraoperative desflurane degradation has been reported with carboxyhemoglobin levels as high as 36%.⁷ Although there was no evidence of patient harm in this case, morbidity or mortality could occur at this level in patients with concurrent disease ([Chap. 125](#)). The true incidence of CO exposure during clinical anesthesia is unknown. Routine detection of intraoperative CO exposure is now possible using multiwavelength pulse cooximeters, but these more expensive devices are not yet widely used, and conventional pulse oximeters that are routinely used in ORs cannot detect CO.⁸

Carbon monoxide production is inversely proportional to the water content of CO_2 absorbents. Soda lime (a granular mixture of calcium, sodium, and potassium hydroxide) is the most frequently used CO_2 absorbent. It is sold wet (13%–15% water by weight), but may dry with high gas-inflow rates. Higher concentrations of CO are most apt to be present during the first case after a weekend because of drying of CO_2 absorbent from a continuous inflow of dry oxygen over the weekend if the anesthesia machine has not been used.¹⁷

Other factors influence the concentration of CO that may result from anesthetic degradation, including temperature (higher temperature increases CO formation), type of absorbent, choice of anesthetic, and concentration of anesthetic. Strong alkalis, such as potassium and sodium hydroxide, initiate the reaction that forms CO.

Mass spectrometry (available in some ORs) cannot directly detect CO because its molecular weight is equivalent to that of nitrogen, a gas usually present in much greater amounts. In addition, detection of CO by fragmentation products is not possible by mass spectrometry because CO_2 is present in greater amounts and has similar fragmentation products.

Unfortunately, the diagnosis of CO poisoning during anesthesia is difficult because the main clinical features of toxicity are masked by anesthesia, and no routinely available means can identify CO within the breathing circuit or detect when the CO_2 absorbent has been desiccated. Delayed neurologic sequelae from intraoperative CO poisoning are likely missed on the anesthesiologist's postoperative patient evaluation.⁵⁸

The product labels of desflurane and isoflurane have been altered to include a precaution that the CO_2 absorbent should be replaced when a practitioner suspects the absorbent is desiccated. However, the problem associated with this warning is the lack of a reliable method for determining when the absorbent is fully or partially desiccated.

If an anesthetic machine is found with the fresh-gas flow on at the beginning of the day, a reasonable practice is to replace the absorbent. Newer CO_2 absorbents that are less likely to degrade anesthetics are now available. These newer absorbents have decreased amounts of strong bases.

LONG-TERM USE OF HALOGENATED ANESTHETICS IN INTENSIVE CARE UNITS

Halogenated anesthetics have been used since the 1990s in intensive care units (ICUs) for long-term sedation of patients receiving mechanical ventilation since the 1990s and more recently as part of the treatment for patients with refractory status epilepticus. Use has been limited by concerns regarding atmospheric pollution and high costs (because of a lack of rebreathing systems in the ICU). The development of anesthetic-conserving devices for use with ICU ventilators has addressed these issues. Potential advantages include more rapid wakeup and shorter times to extubation with minimal risk of toxicity.³²

Clinical studies report the use of isoflurane and sevoflurane for ICU sedation. In one study, 19 patients were mechanically ventilated for more than 24 hours in the ICU with sevoflurane used for sedation.³² Toxic effects of sevoflurane were not found even though serum fluoride concentrations often exceeded 50 μmol (the concentration suggested to be the nephrotoxic threshold).¹²

Isoflurane is being used as a first-choice for long-term sedation during mechanical ventilation in some ICUs. Experimental models demonstrate that isoflurane is potentially neurotoxic, primarily through induction of neuronal apoptosis. In rats, isoflurane substantially decreases local glucose utilization in various brain regions, including the thalamus.

Reversible psychomotor dysfunction was reported in 3.6% of 335 patients who received isoflurane for more than 12 hours as a primary sedative during mechanical ventilation in a general ICU.⁴ Psychomotor dysfunction occurred in 42% of patients age 4 years or younger but in only 1.3% of patients older than 4 years. The psychomotor dysfunction only occurred in patients who received the isoflurane for greater than 24 hours.

Isoflurane is an alternate treatment for patients with refractory status epilepticus. Reversible magnetic resonance imaging (MRI) abnormalities developed in two patients who received inhaled isoflurane for a prolonged time (35 and 85 days).¹⁹ Serial MRIs demonstrated the development of hyperintense T2 signals involving the medulla, cerebellar cortex, deep cerebellar nuclei, thalamus, and hypothalamus bilaterally. These abnormalities improved after discontinuation of the isoflurane.

CHRONIC EXPOSURE TO WASTE ANESTHETIC GASES

Waste anesthetic gases are defined as inhalation gases and vapors that are released into work areas associated with or adjacent to the administration of a gas or volatile liquid for anesthetic purposes. Because anesthesia machines are not airtight and consist of hundreds of parts, it is inevitable that clinical personnel will be exposed to waste anesthetic gases. Exposure to waste anesthetic gas produces short- and long-term effects. Common short-term effects are lethargy and fatigue in staff members who are exposed to significant quantities of waste anesthetic gas. Chronic long-term effects correlate with the concentration of gas and duration of exposure. Animal studies demonstrate that exposure to high concentrations of nitrous oxide and halogenated xenobiotics can cause cellular, mutagenic, carcinogenic, and teratogenic effects.

The US government has been involved with the regulation and management of waste anesthetic gas since 1970. The OR environment in this country is highly regulated and monitored, but exposure limits vary in other countries and can exceed the concentrations permitted in the United States. Even in a modern working environment with low-leakage anesthesia machines, scavenging systems, and high room ventilation exchange rates, exposure to inhalational anesthetics could not be kept below acceptable threshold concentrations in all cases. However, a cause-and-effect relationship between human exposure to waste anesthetic gases and poor reproductive outcomes could not be identified in an analysis requested by the American Society of Anesthesiologists.¹⁰

Dentists and dental assistants are often exposed to greater concentrations of waste anesthetic gases than are individuals working in well-vented ORs. An epidemiologic survey compared 15,000 dentists who used nitrous oxide in their practices to 15,000 dentists who did not.⁹ A 1.2- to 1.8-fold increase in hepatic, kidney, and neurologic disease was found in the dentists and their chair-side assistants who were chronically exposed to trace concentrations of nitrous oxide. For those with heavy office use of nitrous oxide, a fourfold increase in the incidence of neurologic complaints compared with the nonexposed group was observed. Female dental assistants who were exposed to nitrous oxide had a two- to threefold increase in spontaneous abortion rates, reduced fertility, and a higher rate of congenital abnormalities in their offspring.⁹

ABUSE OF HALOGENATED VOLATILE ANESTHETICS

Fatal or life-threatening complications occur when halogenated inhalational anesthetics are used for nonanesthetic purposes such as suicide attempts, mood elevation, and topical treatment of herpes simplex labialis. When ingested, halothane usually produces gastroenteritis with vomiting followed by depressed levels of consciousness, hypotension, shallow breathing, bradycardia with extrasystoles, and acute respiratory distress syndrome (ARDS). Coma usually resolves within

72 hours.^{14,57} The diagnosis should be suspected when these features occur in a patient with the sweet or fruity odor of halothane on the breath. Supportive care, including endotracheal intubation and nasogastric lavage, should be provided. Full recovery can occur without permanent organ injury.

Intravenous injections of halothane may occur as a suicide attempt or unintentionally during anesthesia induction. A young patient who was found unconscious and hypotensive with ARDS after self-administered IV injection of halothane was not successfully resuscitated.⁶ A 16 year-old girl received an unintentional IV injection of 2.5 mL of halothane during anesthesia induction.⁴⁹ She became unconscious and apneic within 30 seconds but began to awaken within 2 to 3 minutes. Four hours later, she developed ARDS but subsequently made a full recovery.

Transient coma and apnea probably are secondary to a halothane bolus reaching the brain on its first pass through the bloodstream. Redistribution then occurs, explaining the rapid awakening. The ARDS that develops after injection of halothane may result from a direct toxic effect of high concentrations of this hydrocarbon on the pulmonary vascular bed. After injection, the anesthetic likely travels as a bolus during the first passage through the pulmonary circulation because of its poor solubility in blood.

Hospital personnel are involved in most reported cases of halothane abuse by inhalation.⁴⁶ Inhalation of halothane produces a pleasurable sensation similar to that described with glue sniffing ([Chap. 84](#)). Death may result from upper airway obstruction after loss of consciousness or from dysrhythmias. Death occurred in a student nurse anesthetist suggested to have applied a full 250 mL bottle of enflurane over 3 hours to “cold sores” on her lower lip.²⁸

SUMMARY

- Inhalational anesthetics remain a popular choice for maintenance of anesthesia because of their safety and titratability.
- Toxicity is uncommon and can result from a variety of mechanisms.
- Health care practitioners who use these anesthetics should be knowledgeable about their pharmacology and potential toxicity.

69 NEUROMUSCULAR BLOCKERS

Kenneth M. Sutin

HISTORY AND EPIDEMIOLOGY

Curare is the generic term for the resinous arrowhead poisons used to paralyze hunted animals.¹⁰⁴ The curare alkaloids are derived from the bark of the Strychnos vine, and the most potent alkaloids, the toxiferines, are derived from Strychnos toxifera. Fortunately for the hunters who used curare, ingestion of their prey did not cause paralysis. Sir Walter Raleigh discovered the use of curare in Guyana in 1595, and he was the first person to bring curare to Europe. Curare played a pivotal role in the discovery of the mechanism of neuromuscular transmission. In 1844, Claude Bernard placed a small piece of dry curare under the skin of a live frog and observed that the frog became limp and died.⁷ He performed an immediate autopsy and discovered that the heart was beating. Because direct muscle stimulation produced contraction but nerve stimulation did not, Bernard concluded that curare paralyzed the motor nerves. He later observed, however, that bathing the isolated nerve did not affect neuromuscular transmission, leading him to conclude: “Curare must act on the terminal plates of motor nerves.”¹⁵ Curare was also used by Nobel Laureate physiologists Charles Sherrington, John Eccles, and Bernard Katz to further elucidate neuromuscular physiology. Its first clinical use was described in 1878 when Hunter used curare to treat patients with tetanus and seizures.¹⁰⁴ In 1932, Raynard West used curare to reduce the muscular rigidity of hemiplegia.¹⁰⁴ The use of curare (d-tubocurarine) in anesthesia spanned almost 60 years until it was replaced by superior agents that caused less histamine release and hypotension.

More recent nonmedical uses of succinylcholine have been less benign.² The anesthesiologist Dr. Carl Coppolino was accused of murdering his wife in 1965 by succinylcholine injection.⁷⁰ In 1983, shortly after Dr. Michael Swango began his internship at Ohio State University Hospital, patients began dying inexplicably, and he was relieved of his duties.⁹⁷ After multiple residencies and jobs over 14 years, extending as far as Mnene Hospital in Zimbabwe, the prosecution secured Swango’s guilty plea for the murder of three victims. The toxicologic analysis of the remains of the 7 year-old victim revealed succinylcholine in the liver and gallbladder and its metabolite succinylmonocholine in multiple organs, which assisted in the Swango conviction.

With the advent of new modalities of drug delivery, toxicologists must be attuned to possible malicious intent. Emergency personnel responding to a 911 call observed the widow removing an insulin pump reservoir from her dead husband’s body with the stated intent to donate the costly equipment.⁴ A natural cause of death was presumed, yet surprisingly, forensic analysis revealed etomidate and laudanosine (a metabolite of atracurium) in the victim’s liver.

Understanding the pharmacokinetics of the depolarizing and nondepolarizing neuromuscular blockers (NMBs) improves care in the emergency department, intensive care unit (ICU), and operating room. Understanding and early recognition of the complications of each NMB limit associated morbidity and mortality.

MECHANISM OF NEUROMUSCULAR TRANSMISSION AND BLOCK

The purpose of an NMB is to selectively and reversibly inhibit transmission at the skeletal neuromuscular junction (NMJ). All NMBs possess at least one positively charged quaternary ammonium moiety that binds to the postsynaptic nicotinic acetylcholine (nACh) receptor at the NMJ, inhibiting its normal activation by acetylcholine (ACh). The nACh receptor is a ligand-gated ion channel that consists of four different protein subunits in a pentameric structure surrounding a central channel. The nACh receptor found in human skeletal muscle is present in two primary forms: a mature type found at the NMJ ($\alpha\beta\epsilon\delta$) or as a fetal (immature) type found on muscle at extrajunctional regions of the muscle fiber ($\alpha\alpha\beta\gamma\delta$). Before discussing the mechanism of neuromuscular block, it is first helpful to understand normal neuromuscular transmission and excitation–contraction coupling (Fig. 69–1).

FIGURE 69–1. Excitation–contraction coupling in skeletal muscle. At the neuromuscular junction, acetylcholine (●) released from the presynaptic nerve terminal crosses the 50-nm synaptic cleft to reach the nicotinic acetylcholine (nACh) receptor (■). When agonist simultaneously occupies both receptor sites, this ion channel opens, becoming nonselectively permeable to monovalent cations, resulting in an influx of Na^{+} and an efflux of K^{+} . This produces local membrane depolarization (end plate potential), which, in turn, opens voltage-activated Na^{+} channels (■). A depolarization of sufficient amplitude generates a propagated muscle action potential (MAP), which is conducted along the muscle membrane and down the transverse (T) tubules. In the T tubule, the MAP triggers a voltage-activated calcium channel, the dihydropyridine receptor (DHP) (■), which then activates the skeletal muscle ryanodine receptor (RyR) channel (■). To allow the fastest activation of mammalian skeletal muscle, calcium diffusion is not necessary for activation of RYR-1; instead, there is a direct electrical (protein) linkage between the dihydropyridine receptor and the ryanodine receptor.²⁹ Active ATPase driven calcium reuptake terminates muscle contraction. Many factors influence the activity of the RYR-1 channel, including Ca^{2+} , Mg^{2+} , and anesthetic drugs such as inhalational anesthetics that accelerate Ca^{2+} release in persons susceptible to malignant hyperthermia. Antagonists such as conotoxin are red and agonists such as nicotine are green.

Therapeutic and toxicologic skeletal muscle paralysis may occur by several mechanisms. For example, tetrodotoxin blocks voltage-sensitive sodium channels, preventing action potential conduction in the motor neuron. On the other hand, botulinum toxin blocks ACh release from the presynaptic neuron by inhibiting the binding of ACh-containing vesicles to the neuronal membrane in the region of the synaptic cleft. Modulation of postsynaptic ACh receptor activity at the NMJ may produce paralysis by one of two mechanisms: depolarizing (phase I block) and nondepolarizing (phase II block). Succinylcholine is the only depolarizing neuromuscular blocker (DNMB) in current clinical use. Nicotine at high doses may also cause a depolarizing block. All other drugs discussed are nondepolarizing neuromuscular blockers (NDNMBs).

The process of depolarizing neuromuscular blockade requires several steps. First, two molecules of succinylcholine must bind to each α site of the nACh receptor. This action causes a prolonged open state of the nACh receptor ion channel. The initial depolarization generates a muscle action potential and usually causes brief contractions (fasciculations). In contrast to ACh, succinylcholine is not hydrolyzed efficiently by junctional (true) acetylcholinesterase (AChE); thus, the effect of succinylcholine lasts much longer than ACh. Persistence of succinylcholine at the ACh receptor causes a sustained local muscle endplate depolarization that, in turn, causes the voltage-gated sodium channel in the perijunctional region to remain in a prolonged inactive state, inducing a desensitization block. The muscle is temporarily refractory to presynaptic release of ACh (phase I block).

The NDNMBs cause skeletal muscle paralysis by competitively inhibiting the effects of ACh and thus preventing muscle depolarization. One molecule of an NDNMB bound to a single nACh receptor (also on the α site) is sufficient to competitively inhibit normal channel activation. Because the NDNMBs do not block voltage-gated sodium channels on the skeletal muscle membrane, direct electrical stimulation with a current sufficient to cause membrane depolarization will still elicit a muscular contraction. The NDNMBs are classified by duration of action as ultrashort, short, intermediate, and long. They are also classified by chemical structure as either a synthetic benzylisoquinolinium or an aminosteroid (Table 69–1).

TABLE 69–1. Pharmacology of Selected Neuromuscular Blockers

Generic Name	Class	Duration	Initial Dose (mg/kg) ^{a,b}	Onset (minutes) ^c	Clinical Duration (minutes) ^d
Succinylcholine	Depolarizer	Ultrashort	0.6–1	1–1.5	3–7
Atracurium	Nondepolarizer,	Intermediate	0.4	2–4	20–40
Cisatracurium	benzylisoquinolinium	Intermediate	0.1	2–4	20–40
Pancuronium	Nondepolarizer,	Long	0.1	3–6	60–90
Rocuronium	aminosteroid	Intermediate	0.6	1.5–3	30–40
Vecuronium		Intermediate	0.1	2–4	20–40
	Renal Excretion (%) ^e	Biliary Excretion (%) ^f	Metabolite	Histamine Release	Effect on Heart Rate
Succinylcholine	<10	Minimal	Succinic acid	Minimal	Bradycardia (rare)
Atracurium	5–10	Minimal	Laudanosine	Minimal	No
Cisatracurium	10–20	Minimal	Laudanosine	No	No
Pancuronium	40–60	10–20	3-Desacetyl-pancuronium ^g	No	Tachycardia
Rocuronium	10–20	50–70	No	No	Tachycardia at high dose
Vecuronium	15–25	40–70	3-Desacetyl-vecuronium ^h	No	No

^aCisatracurium is labeled as milligram of base per milliliter. Other drugs are labeled and packaged as milligram of salt per milliliter. ^bTypical initial dose is approximately $2 \times ED_{95}$ (mg/kg). ^cOnset is time from bolus to 100% block. ^dClinical duration is time from drug injection until 25% recovery of single twitch height. ^ePercent renal excretion in the first 24 hours of unchanged drug; if high, associated with prolongation of clinical effect. ^fPercent biliary excretion in first 24 hours of unchanged drug; if high, associated with prolongation of clinical effect. ^gActive metabolite.

Data from Donati F: Neuromuscular blocking drugs for the new millennium: current practice, future trends—comparative pharmacology of neuromuscular blocking drugs. *Anesth Analg*. 2000;90(suppl):S2–S6; McManus MC: Neuromuscular blockers in surgery and intensive care, part 1. *Am J Health Syst Pharm*. 2001;58:2287–2299; and Murray MJ, Cowen J, DeBlock H, et al: Clinical practice guidelines for sustained neuromuscular blockade in the adult critically ill patient. *Crit Care Med*. 2002;30:142–156.

NDNMBs also block nACh receptors on the prejunctional nerve terminal and inhibit ACh-stimulated ACh production and release⁸⁸ by blocking local autoregulation of available ACh. This effect reduces the available pool of ACh and augments the extent of neuromuscular block.⁹

PHARMACOKINETICS

The NMBs are highly water soluble and relatively insoluble in lipids. Thus, they are rapidly distributed in the extracellular space and very slowly permeate lipid membranes such as the gut, placenta, and the normal blood–brain barrier. For this reason, they are devoid of central nervous system (CNS) effects. Because these drugs distribute in the extracellular space, their dosage is based on ideal body mass. In obese patients, estimation of drug requirement according to total body mass results in the administration of an excessive dose.

The speed of onset of an NMB is inversely related to its molar potency (ie, ED_{95} expressed as moles NMB drug per kilogram body weight).^{52,53} Stated differently, the greater the affinity of the NDNMB for the ACh receptor, the fewer molecules per kilogram of tissue are required to produce a given degree of ACh receptor occupancy. Atracurium is the only

drug that does not follow this generalization because it is a mixture of 10 isomers, each having a different receptor affinity (cisatracurium consists of only one isomer).

In general, small, fast-contracting muscles such as the extraocular muscles are more susceptible to neuromuscular block than are larger, slower muscles such as the diaphragm. This is the so-called respiratory sparing effect. After an intravenous (IV) bolus of an NDNMB, paralysis of the diaphragm is coincident with paralysis of laryngeal muscles because high tissue perfusion results in rapid drug distribution and diffusion into the NMJ of all tissues.²¹ However, recovery from an NMB is fastest for the diaphragm and intercostal muscles; intermediate for the large muscles of the trunk and extremities; and slowest for the adductor pollicis, larynx, pharynx, and extraocular muscles.²¹

COMPLICATIONS OF NEUROMUSCULAR BLOCKERS

Complications associated with the use of NMBs include (a) problems associated with the care of a paralyzed patient (eg, undetected hypoventilation resulting from ventilator or airway problems, impaired ability to monitor neurologic function, unintentional patient awareness, peripheral nerve injury, deep vein thrombosis, and skin breakdown); (b) immediate side effects; and (c) effects occurring after prolonged drug exposure.^{77,78}

Consciousness

Even though NMB drugs do not affect consciousness, misconceptions about these drugs persist.⁶⁷ The pupillary light reflex, an important indicator of midbrain function, is preserved in healthy subjects who receive NDNMBs³⁸ because pupillary function is mediated by muscarinic cholinergic receptors, for which the NMBs have no affinity.

Histamine Release

Muscle relaxants may elicit dose- and injection rate-related nonimmunologic (non-IgE-mediated) histamine release from tissue mast cells by an uncertain mechanism (Table 69–1). The drugs most commonly associated with histamine release are atracurium and succinylcholine.⁷³

Anaphylaxis

Perioperatively, anaphylactic reactions are rare, with an incidence of 1:3500 to 1:20,000, and up to 60% are related to NMBs.⁷³ Rocuronium is responsible for 43% and succinylcholine for 23% of all NMB-associated anaphylaxis. In up to half of these patients, there is no prior exposure to an NMB, and cross-sensitization by another allergen is the likely explanation.⁶⁰ Pancuronium is the drug that is least associated with serious allergic reactions.¹⁰³

Control of Respiration

At subparalyzing doses, NDNMBs blunt the hypoxic ventilatory response (HVR) but not the ventilatory response to hypercapnia.^{26,27} HVR returns to normal when chemical paralysis is completely reversed. Hypoventilation resulting from blunting of the HVR, especially when combined with the residual effects of other drugs used during anesthesia (eg, opioids or inhalational anesthetics), may cause delayed respiratory failure (eg, after general anesthesia).

Autonomic Side Effects

Nicotinic ACh receptors found in autonomic ganglia, similar to those at the NMJ, are pentamers composed of α and β subunits. In general, they are less susceptible to block by NMBs.⁶⁸ There is one notable exception. At the same dose that produces neuromuscular block, tubocurarine also blocks nACh receptors at the parasympathetic ganglia, causing tachycardia, and at the sympathetic ganglia, blunting the sympathetic response.⁹² In combination with tubocurarine-related histamine release, the sympathetic block may cause significant hypotension, especially in patients with heart failure or hypovolemia.⁹ This is an important reason why tubocurarine is no longer available in the United States.

The muscarinic receptors (M_1 – M_5) are members of the seven-transmembrane G-protein–coupled receptor family. As such, they are structurally unique and mostly unaffected by NMBs. At clinical doses, pancuronium elicits dose- and injection rate–related increases in heart rate, blood pressure, cardiac output, and sympathetic tone.^{22,93,98} This is attributed to a selective block of parasympathetic transmission at the cardiac muscarinic receptors (atropinelike effect),⁹³ block of presynaptic (feedback) muscarinic receptors at sympathetic nerve terminals, and perhaps an indirect norepinephrine-releasing effect at postganglionic fibers.²²

Dysrhythmias, including bradycardia, junctional rhythms, ventricular dysrhythmias, and cardiac arrest, occur rarely after use of succinylcholine. Dysrhythmias most likely result from stimulation of the cardiac muscarinic receptors and can be prevented by pretreatment with 15 to 20 μ g/kg IV of atropine. Bradycardia is uncommon, but it may be especially severe

in children during anesthetic induction when large or repeated doses of succinylcholine are given.

Interactions of Neuromuscular Blockers with Other Xenobiotics and Pathologic Conditions

NMBs have significant interactions with many xenobiotics and coexisting medical conditions. These interactions may affect the neuromuscular system at any level, from the CNS to the muscle itself^{84,102} (Table 69–2). In most neuromuscular diseases, such as muscular dystrophy, Guillain-Barré syndrome, myasthenia gravis, and postpolio syndrome, the sensitivity to NDNMB is increased, so a small dose of NMB produces a profound degree of block.^{1,11,40} However, persons with myasthenia gravis typically demonstrate resistance to the effects of succinylcholine.^{1,11} In individuals with myopathy in whom the specific cause is not yet known, it is prudent to avoid succinylcholine because of the possible sensitivity to malignant hyperthermia (MH), hyperkalemia, or rhabdomyolysis; in place of succinylcholine, a short-acting NDNMB can be used (to lessen the chance of prolonged weakness).

TABLE 69–2. Effect of Prior Administration of Xenobiotics on Subsequent Response to Succinylcholine or Nondepolarizing Neuromuscular Blockers

<i>Antibiotic</i>	<i>Response to Succinylcholine</i>	<i>Response to Nondepolarizer</i>	<i>Comments</i>
Aminoglycosides (eg, amikacin, gentamicin)	Potentiates	Potentiates	Dose-related decrease in presynaptic ACh release. May decrease postjunctional response to ACh. Partially reversible with calcium administration. Effect of neostigmine unpredictable.
Anticholinesterase, peripheral acting: neostigmine, edrophonium	Prolongs succinylcholine (except edrophonium)	No effect	Neostigmine, pyridostigmine, and physostigmine inhibit plasma AChE and prolong succinylcholine block. Edrophonium does not inhibit plasma cholinesterase.
Anticholinesterase, centrally acting: donepezil	Potentiates		Inhibits AChE (junctional >> plasma); long half-life (70 hours).
β -Adrenergic antagonist: propranolol	Potentiates in cats, effects in humans uncertain	Potentiates	When given alone, may unmask myasthenic syndrome. Blocks ACh binding at postsynaptic membrane. Reversal of block with neostigmine may cause severe bradycardia.
β -Adrenergic antagonist: esmolol	Mild prolongation	Slows onset of rocuronium	Competes for PChE.
Botulinum toxin	?	Early potentiation, delayed resistance	Acutely, subclinical systemic denervation leads to hypersensitivity.
Calcium channel blockers	Potentiates	Potentiates	Causes calcium channel block pre- and postjunctionally. Verapamil has local cholinesterase inhibitor effect on nerve. May inhibit block reversal by cholinesterase inhibitor.
Carbamazepine	?	Inhibits, shortened duration	Chronic therapy causes resistance to NDNM, except for atracurium.
Cardioactive steroids	More prone to cardiac dysrhythmias	Pancuronium increases catecholamines and may cause dysrhythmias	
Dantrolene	?	Potentiates	Blocks excitation-contraction coupling by blocking ryanodine receptor channel in sarcoplasmic reticulum of skeletal muscle.
Furosemide <10 μ g/kg 1–4 mg/kg	Potentiates/inhibits	Potentiates/inhibits	Biphasic dose response in cats: protein kinase inhibition at low doses and phosphodiesterase inhibition at high doses. Diuretic-related hypokalemia potentiates pancuronium in cats.
Glucocorticoids	?	Inhibits	Chronic steroid use induces resistance to pancuronium and decrease plasma cholinesterase activity by 50%. Steroids \pm NDNM associated with myopathies.
Inhalational anesthetics: isoflurane	Potentiates	Potentiates	Decrease CNS activity and potentiates NMB in anesthetic doses: dependent fashion (postsynaptic and muscle effects). Halothane causes less muscle relaxation than isoflurane.
Lidocaine	Potentiates	Low-dose potentiates block. High-dose inhibits nerve terminals and blocks ACh binding site at postsynaptic membrane.	The fast Na^+ channel blockers decrease action potential propagation, ACh release, postsynaptic membrane sensitivity, and muscle excitability. Weak inhibitor of PChE.
Lithium carbonate	Prolongs onset and duration	Prolongs effect of pancuronium	Inhibits synthesis and release of ACh. Lithium alone may cause myasthenic reaction.
Magnesium	Potentiates; may block fasciculations	Potentiates; may also prolong block	Decreases prejunctional ACh release, postjunctional membrane sensitivity, and muscle excitability.
NDNM: pancuronium, vecuronium, rocuronium	"Precurarization" with NDNM shortens the onset and decreases side effects of succinylcholine. Pancuronium increases block duration.	Chronic NDNM induces resistance to their effect. Mixing different NDNMs may cause greater than additive effects, especially combining pancuronium with tubocurarine or metocurine.	Prior NDNM inhibits plasma AChE and prolongs mivacurium and succinylcholine block. Rank order: pancuronium > vecuronium > atracurium. Heterozygote for atypical PChE may develop phase II block when given succinylcholine and pancuronium.
Organic phosphorus compounds	Potentiates	?	Irreversible PChE inhibitor. May totally block enzyme activity.
Phenelzine (MAOI)	Prolongs	?	Decreases PChE activity.
Phenytoin	?	Resistant, shortened duration	Acutely, potentiates NDNM paralysis. With chronic use (except for atracurium), phenytoin induces resistance to NDNM and increases drug metabolism. This increases the initial dose and decreases the repeat dosing interval.
Polypeptide antibiotics: polymyxin	Potentiates	Potentiates	May cause severe weakness. May induce postsynaptic neuromuscular block. Neostigmine increases block.

Succinylcholine	Small initial dose of succinylcholine may be used to limit muscular fasciculations.	Pancuronium and vecuronium slightly prolonged by prior succinylcholine	
Theophylline		Inhibits	Pancuronium and theophylline may increase cardiac dysrhythmias.
Cyclic antidepressants (CA)			Pancuronium and CA may cause cardiac dysrhythmias due to sympathetic effects.

ACh = acetylcholine; AChE = acetylcholinesterase; CA = cyclic antidepressant; MAOI = monoamine oxidase inhibitor; NDNMB = nondepolarizing neuromuscular blocker; NMB = neuromuscular blocker; NMJ = neuromuscular junction. Data from Crowe S, Collins L: Succinethonium and donepezil: a cause of prolonged paralysis. *Anesthesiology*. 2003;98:574–575; Raciuno F, Grandi L, Saliven P, et al: Sensitivity to vecuronium after botulinum toxin administration. *J Neurosurg Anesthesiol*. 1997;9:140–153; Fleming NW, Macres S, Antognini JF, Vengco J: Neuromuscular blocking action of succinethonium after antagonism of vecuronium by edrophonium, pyridostigmine or neostigmine. *Br J Anaesth*. 1996;77:492–495; Kaeser HE: Drug-induced myasthenic syndromes. *Acta Neurol Scand Suppl*. 1984;100:39–47; Kato M, Hashimoto Y, Horinouchi T, et al: Inhibition of human plasma cholinesterase and erythrocyte acetylcholinesterase by nondepolarizing neuromuscular blocking agents. *J Anesth*. 2000;14:30–34; Ostergaard O, Engback J, Viby-Mogensen J: Adverse reactions and interactions of the neuromuscular blocking drugs. *Med Toxicol Adverse Drug Exp*. 1989; 4:351–368; and Viby-Mogensen J: Interaction of other drugs with muscle relaxants. In: Katz RL, ed. *Muscle Relaxants: Basic and Clinical Aspects*. New York: Grune & Stratton; 1985:233–256.

Many pathologic conditions potentiate the duration or intensity of NDNMBs, such as respiratory acidosis, hypokalemia, hypocalcemia, hypermagnesemia, hypophosphatemia, hypothermia, shock, and liver or kidney failure.⁸⁷ Alternatively, sepsis and inflammatory conditions are associated with mild resistance to the effects of NDNMBs.⁷⁹

SUCCINYLCHOLINE

Pharmacology

Succinylcholine is a bis-quaternary ammonium ion composed of two molecules of ACh joined end to end at the acetate groups.²⁴ After a conventional IV induction dose (1 mg/kg), typical serum concentrations are approximately 62 µg/mL.⁸¹

Succinylcholine is hydrolyzed primarily by plasma cholinesterase (PChE, also known as pseudocholinesterase or butyrylcholinesterase; BChE, EC 3.1.1.8) and to a slight extent by alkaline hydrolysis. Hydrolysis is a two-step reaction; first succinylmonocholine and choline are formed, and then succinic acid and choline are formed (the latter two are normal products of intermediary metabolism). The first reaction is approximately six times faster than the second reaction. Less than 3% of the administered dose is excreted unchanged in the urine.³⁶ After an IV bolus, the plasma succinylcholine concentration increases abruptly, and there is a rapid onset of NMJ block. Later, the plasma succinylcholine concentration undergoes a rapid decline as a result of drug redistribution to extravascular tissues and hydrolysis in plasma. Finally, succinylcholine leaves the NMJ to reenter the plasma as a result of reversal of the concentration gradient.^{35,48}

Succinylcholine 1 mg/kg IV usually increases cerebral blood flow, cortical electrical activity, intracranial pressure,⁵⁴ and intraocular pressure, especially in lightly anesthetized patients. These effects, when they occur, are usually modest and of no clinical significance.

Toxicology

The important adverse drug reactions associated with succinylcholine include anaphylaxis, prolonged drug effect, hyperkalemia, acute rhabdomyolysis in patients with muscular dystrophy, MH in susceptible patients, muscle spasms or trismus in patients with myotonia congenita, and cardiac dysrhythmias.

Prolonged Effect

The effects of succinylcholine may last for several hours if metabolism is slowed because of decreased PChE concentration, abnormal PChE activity (genetic variant or drug inhibition), or a phase II block.¹⁷ Acquired PChE deficiency may be caused by hepatic disease, malnutrition, plasmapheresis, or pregnancy.¹⁷ Inactivation of PChE may be caused by fluoride poisoning, organic phosphorus compounds, and carbamates. However, even with only 20% to 30% of normal PChE activity, the clinical duration of succinylcholine is less than doubled.³¹

Many genetic variants of PChE are known. The most common atypical PChE (atypical type, homozygous; incidence 1:3000) can be assayed by its resistance to inhibition by the local anesthetic dibucaine.⁸⁵ A history of uneventful exposure to succinylcholine excludes the possibility of atypical PChE except in the case of hepatic transplantation. Dibucaine inhibits the ability of normal PChE to hydrolyze benzoylcholine by more than 70% (ie, dibucaine number >70), heterozygous atypical PChE by 40% to 60%, and homozygous atypical PChE by 30% or less. Fresh-frozen plasma or PChE concentrates may be infused to hasten recovery in the case of a genetic enzyme defect or an acquired PChE deficiency. However, to avoid the risks of transfusion, it is best to simply keep the patient sedated, intubated, and ventilated until the drug is metabolized. In this setting, spontaneous reversal usually occurs within 3 to 4 hours, although in rare cases, full recovery requires up to 12 hours.¹⁷ When the duration of succinylcholine is very prolonged, blood samples should be

drawn for measurement of PChE concentration and activity.

Prolonged nondepolarizing block may occur when unusually large IV doses of succinylcholine (3–5 mg/kg) are given over minutes.⁶² This is called phase II block, and it can be partially reversed by neostigmine.

Hyperkalemia

Succinylcholine 1 mg/kg IV typically causes serum K^+ concentration to increase within minutes by approximately 0.5 mEq/L both in normal individuals and in persons with kidney failure. The acute hyperkalemic response to succinylcholine is greatly exaggerated with coexisting myopathy or proliferation of extrajunctional muscle ACh receptors. However, the mortality is highest (approaching 30%) when rhabdomyolysis is present.³⁹ Severe, precipitous, potentially life-threatening hyperkalemia also occurs after succinylcholine administration in several conditions associated with proliferation of ACh receptors. These conditions include denervation (head or spinal cord injury, stroke, neuropathy, prolonged use of NDNMBs), muscle pathology (direct trauma, crush or compartment syndrome, muscular dystrophy), critical illness (hemorrhagic shock, neuropathy, myopathy, prolonged immobility), thermal burn or cold injury, and sepsis lasting several days (eg, intraabdominal infections). After a neurologic injury, susceptibility to hyperkalemia begins within 4 to 7 days and may persist indefinitely. In patients who have been in the ICU for more than one week, a prudent course is to avoid succinylcholine altogether because of the risk of hyperkalemic cardiac arrest, which is associated with a mortality rate of at least 19%.^{6,8,39} Severe hyperkalemia is modified, but not prevented, by a dose of an NDNMB sufficient to prevent succinylcholine-induced muscle fasciculations.

Severe or even fatal hyperkalemia is reported in a few patients who received succinylcholine immediately after exsanguinating hemorrhage or massive trauma. The mechanism for this condition differs from that after neurologic injury because of inadequate time for proliferation of extrajunctional ACh receptors. Succinic acid, a tricarboxylic acid cycle intermediate (which is also a metabolite of succinylcholine), facilitates activation of voltage-gated sodium channels in a dose-dependent fashion, increasing skeletal muscle excitability.⁴¹ In hemorrhagic shock, accumulation of succinic acid as a result of cell breakdown and anaerobic metabolism possibly augments the potassium-releasing effect of succinylcholine.

Rhabdomyolysis

Severe hyperkalemia rarely occurs in the absence of a clinical history that readily discloses an obvious risk factor, with one important exception. Acute or delayed onset of rhabdomyolysis, hyperkalemia, ventricular dysrhythmias, cardiac arrest, and death are reported in apparently healthy children who subsequently were found to have an undiagnosed myopathy.⁵⁸ Since March 1995, a black box warning on the package insert has stated that succinylcholine should be avoided in elective surgery in children, particularly in children younger than 8 years of age, because of the small risk of a previously undiagnosed skeletal myopathy, especially Duchenne muscular dystrophy. Sudden cardiac arrest occurring immediately after succinylcholine administration should always be assumed to be caused by hyperkalemia. If fever, muscle rigidity, hyperlactatemia, or metabolic and respiratory acidosis also is present, the presumptive diagnosis of MH should prompt immediate therapy with dantrolene.

Malignant Hyperthermia

MH is a syndrome characterized by extreme skeletal muscle hypermetabolism. It is most often initiated after exposure to an anesthetic that triggers a cycle of abnormal calcium release from the skeletal muscle sarcoplasmic reticulum, and it can have a variable presentation.⁹⁰ Although MH is strongly associated with certain myopathies, especially King-Denborough syndrome, central core disease, and multiminicore disease, the disorder is also associated with certain enzyme deficiencies (McArdle disease, carnitine palmitoyltransferase type II, and myoadenylate deaminase deficiency), myopathies (eg, Duchenne muscular dystrophy, hyperCKemia), and some myotonias. MH typically affects individuals who are otherwise healthy and most have had prior uneventful anesthesia.⁵⁶ It is inherited as an autosomal dominant trait with variable penetrance.⁶⁹ Triggering xenobiotics that can precipitate an attack of MH include succinylcholine and volatile inhalational anesthetics (the prototypical xenobiotic is halothane). In individuals who are considered MH susceptible (MHS), xenobiotics that can be administered safely include NDNMBs, nitrous oxide, propofol, ketamine, etomidate, benzodiazepines, barbiturates, opioids, and local anesthetics.

In human MH, there is a causal association with several unique defects involving a skeletal muscle receptor/regulatory protein, especially defects involving the calcium-activated calcium release channel found in skeletal muscle: the type 1 ryanodine receptor (or RYR-1, chromosome 19q13.1). Mutations of the RYR-1 receptor are detected in 50% to 70% of patients with MH, and more than 200 different mutations are described^{10,44} (Fig. 69–1). The structurally distinct type 2 ryanodine receptor (RYR-2) is the primary type expressed in cardiac muscle, and this could explain why the myocardium is relatively spared in the early phase of MH (with the exception of an acute hyperdynamic response).⁸⁹ Of practical importance, the existence of multiple mutations across multiple alleles means that genetic testing is not likely to prove useful in detecting all MHS individuals or in excluding the risk of MH.

Although the prevalence of a genetic disorder associated with MH is one in 3000 to one in 8500, the observed incidence of fulminant MH in patients exposed to general anesthesia when triggering anesthetic agents are used is one in 62,000 to one in 84,000.^{83,90} Each year in the United States, there are an estimated 700 cases of MH.⁵⁵ In the MHS population, after exposure to anesthesia with known triggers, clinical manifestations develop less than half the time. For this reason, a previous uneventful anesthetic exposure does not preclude development of MH on a subsequent exposure.³ In the operating room, MH most often presents abruptly soon after initial exposure to a triggering anesthetic, but the onset of MH may be delayed several hours during the anesthesia,⁷⁶ or it may occur as long as 12 hours after surgery. In addition, recrudescence of MH can occur within 24 to 36 hours after an initial episode in up to 25% of patients.

The immediate systemic manifestations of MH result from extreme skeletal muscle hypermetabolism. The uncontrolled release of calcium from the terminal cisternae of the sarcoplasmic reticulum causes skeletal muscle contraction. Although generalized muscular rigidity is a specific sign of MH, it is only observed in 40%; masseter spasm is a sensitive finding observed in 27% of MH patients.⁵⁶ Futile calcium cycling by sarcoplasmic Ca^{2+} -ATPase rapidly depletes intracellular ATP and leads to anaerobic metabolism. Clinically, MH presents as skeletal muscle hypermetabolism with an increase in cardiac output and sinus tachycardia. Increased CO_2 production causes hypercapnia. Increased O_2 consumption can cause mixed venous O_2 desaturation (below the normal value of 75%), arterial hypoxemia, anaerobic metabolism, metabolic acidosis, and elevation of lactate concentration, cyanosis, and skin mottling. Excess heat production leads to a rapid increase in core temperature with hyperthermia.⁴² Other clinical findings include tachycardia, cardiac dysrhythmias, hyperkalemia, rhabdomyolysis, and disseminated intravascular coagulopathy.

The earliest signs of MH include an early and rapid increase in CO_2 production, causing an increase in arterial, venous, and end-tidal CO_2 . This is followed by or associated with tachycardia, tachypnea, hypertension or labile blood pressure, and skeletal and jaw muscle rigidity. Despite the name of the syndrome, hyperthermia is not a universal finding in MH, and moreover, it may be a late sign.¹⁰¹ Acute potassium release from skeletal muscle cells may produce life-threatening hyperkalemia. Subsequent rhabdomyolysis may exacerbate the elevation of potassium by causing acute kidney injury. In late-stage MH, cardiac decompensation results from hyperkalemia, heart failure, vascular collapse, or myocardial ischemia (especially with coexisting coronary artery disease). A standardized MH clinical grading scale based on patient history, clinical observations, and laboratory studies is commonly used to rank the qualitative likelihood (ranging from “almost never” to “almost certain”) that an adverse event represents a true episode of MH.⁵⁷ Points are assigned based on the clinical likelihood that observations are inappropriate for a given patient (eg, respiratory acidosis occurring abruptly despite sustained mechanical ventilation).

The differential diagnosis of MH includes antipsychotic malignant syndrome, propofol infusion syndrome, serotonin syndrome, thyroid storm, pheochromocytoma, baclofen withdrawal, malignant syndrome during withdrawal of dopaminergic drugs to treat Parkinson disease, tetanus, meningitis, poisoning by salicylates, amphetamines, cocaine, or antimuscarinics, unintentional intraoperative hyperthermia, heat stroke, and transfusion reactions. Of note, early septic shock is also associated with hypermetabolism, increased cardiac output, and fever, however, in contrast to MH, early septic shock is associated with an elevated mixed venous O_2 saturation (typically >75%).

Rarely, MH is triggered by severe exercise in a hot climate, IV potassium (which depolarizes the muscle membrane), antipsychotics, or infection.^{20,47} There is increased awareness of a possible link between MH and exertional heat illness or exertional rhabdomyolysis (ER; eg, a patient with ER who at a later time developed MH).^{12,13} Most patients with heat-related illness do not have MH, even if, on occasion, some patients have demonstrated a favorable response to dantrolene. Furthermore, a presumptive diagnosis of heat related illness does not necessarily exclude the diagnosis of MH and one must maintain clinical suspicion for possible MH, especially since environmental factors can be a sole precipitating factor in the absence of anesthetics.⁴⁴

One theory of the pathogenesis of MH suggests that MH-triggering xenobiotics interact with an abnormal RYR-1 channel, causing it to stay in a prolonged open state and leading to rapid efflux of calcium from the skeletal muscle sarcoplasmic reticulum into the myoplasm. Succinylcholine prolongs muscle depolarization, leading to elevated myoplasmic calcium concentration. This action initiates accelerated calcium-activated calcium release from the myoplasmic reticulum.³⁹ However, not all cases of MH can be explained by an RYR-1 mutation.³² For example, MH is also associated with defects in the CACNA1S protein that encodes a subunit of the skeletal muscle L-type calcium channel (known as the dihydropyridine receptor) and possibly with certain disorders of sodium channels (observed in the myotonic disorders).^{32,75}

The antidote for MH is dantrolene, and the key aspects of MH therapy are rapid initial diagnosis, discontinuation of triggering anesthetics, and immediate therapy with dantrolene (within minutes). By partially blocking calcium release from skeletal muscle sarcoplasmic reticulum, dantrolene rapidly reverses the signs and symptoms of hypermetabolism (Antidotes in Depth: A21). The precise mechanism of dantrolene activity is not known, but it modulates several calcium pathways.⁴⁴ Before the introduction of dantrolene, the mortality rate of MH was 64%.⁵⁵ When patients with an acute phase MH are treated immediately with dantrolene, removal of triggering agents, and supportive measures (volume resuscitation, active

cooling, control of hyperkalemia), the mortality rate is less than 5%.⁵⁵ Factors associated with an increase in mortality are a muscular body habitus, development of disseminated intravascular coagulation, and a longer duration of anesthesia before the peak in end-tidal carbon dioxide.⁵⁵ Even if administration is delayed for hours or days, dantrolene may still improve survival after an acute phase of MH. Patients with significant dysrhythmias can be treated with standard antidysrhythmics; however, calcium channel blockers must not be given with dantrolene because they may precipitate hyperkalemia and severe hypotension⁹¹ (Table 69–3).

Notes:

- Each vial of dantrolene contains 20 mg of dantrolene and 3 g of mannitol. Each vial should be reconstituted with at least 60 mL of sterile, preservative-free water. Dissolution of the lyophilized dantrolene in water is slow and requires thorough mixing.
- The guideline above may not apply to every patient and of necessity must be altered according to specific patient needs.
- Sudden unexpected cardiac arrest in children: Children younger than about 10 years of age who experience sudden cardiac arrest after succinylcholine administration in the absence of hypoxemia and anesthetic overdose should be treated for acute hyperkalemia first. In this situation, calcium chloride should be administered along with means to reduce serum potassium. They should be presumed to have subclinical muscular dystrophy, and a pediatric neurologist should be consulted.

CBC = complete blood count; ICU = intensive care unit; IV = intravenous.

TABLE 69–3. Suggested Therapy for Malignant Hyperthermia (MH)

Acute Phase Treatment of MH

1. Call for help. Immediately summon experienced help when MH is suspected.
2. Discontinue triggers volatile inhalational anesthetics and succinylcholine.
3. Hyperventilate with 100% O₂ with flow ≥ 10 L/min and monitor end-tidal CO₂.
4. Halt procedure as soon as possible, and continue sedation and analgesia with nontriggering agents (eg, opioids and benzodiazepines).
5. Administer dantrolene sodium, initial IV bolus of 2–3 mg/kg followed by additional boluses (every 15 minutes), until signs of MH are controlled (tachycardia, rigidity, increased end-tidal CO₂, hyperthermia). Typically, a total dose of 10 mg/kg IV controls symptoms, but occasionally 30 mg/kg may be required.
6. Monitor core temperature closely (tympanic membrane, nasopharynx, esophagus, rectal, or pulmonary artery) and actively cool the patient with core temperature $>39^{\circ}\text{C}$, (immersion in ice-water slurry, peritoneal or gastric lavage can also be useful, surface cool and/or surface cooling).
7. Hyperkalemia is common and should be treated aggressively with hyperventilation, IV calcium gluconate or chloride, sodium bicarbonate, IV dextrose, and insulin. Hypokalemia should be treated with caution because of the potential for rhabdomyolysis induced hyperkalemia.
8. Sodium bicarbonate. Consider 1–2 mEq/kg if blood gas values not yet obtained, or if clinically indicated.
9. Monitor continuously: electrocardiogram, pulse oximetry, end-tidal CO₂, core temperature, central venous pressure, urine output; and serially measure: arterial and mixed venous blood gases, metabolic profile (especially potassium), calcium, CBC, coagulation indices, and creatine kinase.
10. Dysrhythmias usually respond to dantrolene and correction of acidosis and hyperkalemia. If dysrhythmias persist or are life threatening, standard antidysrhythmics may be used including amiodarone, magnesium, and procainamide
 - Calcium channel blockers (verapamil or diltiazem) are not to be used to treat dysrhythmias because they may cause hyperkalemia and cardiac arrest.
11. Ensure adequate urine output by hydration and/or administration of mannitol or furosemide. Insert a urinary bladder catheter and consider central venous or pulmonary artery catheterization.
- 12 For emergency consultation, refer to the Malignant Hyperthermia Association of the United States (MHAUS) at <http://www.mhaus.org/>. Call the MH Emergency Hotline:
 - Inside United States or Canada, call 800-MH-HYPER (800-644-9737)
 - Outside the United States and Canada, call 001 315-464-7079

Postacute Phase Treatment of MH

1. Observe the patient in an ICU setting for at least 24 hours because recrudescence of MH occurs in 25% of cases, particularly after a fulminant case resistant to treatment. Observe for pulmonary edema, renal failure, and compartment syndrome.
2. Administer dantrolene 1 mg/kg IV q4.6h or 0.25 mg/kg/h by infusion for at least 24 hours after the episode.

3. Serially monitor arterial blood gases, metabolic profile, CBC, creatine kinase, calcium, phosphorus, coagulation indices, urine and serum myoglobin, and core body temperature until they return to normal values.
4. Counsel the patient and family regarding MH and further precautions.
 - For nonemergency patient referrals, contact MHAUS at 800-644-9737, 1 North Main Street, PO Box 1069, Sherburne, NY 13460.
 - Report patients who have had an acute MH episode to the North American MH Registry of MHAUS at 888-274-7899.
 - Alert family members to the possible dangers of MH and anesthesia.
5. Recommend an MH medical ID tag or bracelet for the patient, which should be worn at all times.

Notes:

- Each vial of dantrolene contains 20 mg of dantrolene and 3 g of mannitol. Each vial should be reconstituted with at least 60 mL of sterile, preservative-free water. Dissolution of the lyophilized dantrolene in water is slow and requires thorough mixing.
- The guideline above may not apply to every patient and of necessity must be altered according to specific patient needs.
- Sudden unexpected cardiac arrest in children: Children younger than about 10 years of age who experience sudden cardiac arrest after succinylcholine administration in the absence of hypoxemia and anesthetic overdose should be treated for acute hyperkalemia first. In this situation, calcium chloride should be administered along with means to reduce serum potassium. They should be presumed to have subclinical muscular dystrophy, and a pediatric neurologist should be consulted.

CBC = complete blood count; ICU = intensive care unit; IV = intravenous.

Persons who have experienced a possible episode of MH or have a positive family history should be referred to the Malignant Hyperthermia Registry and may be considered for muscle biopsy and muscle testing. The fresh tissue specimen is placed in a tissue bath perfused with Krebs solution, and halothane or caffeine is added. According to the North America Malignant Hyperthermia Group, an MH-susceptible individual is one who demonstrates a positive muscle contraction in response to either halothane or caffeine.

Muscle Spasms

Masseter muscle rigidity (MMR) was observed in 0.3% to 1.0% of children when general anesthesia was induced with succinylcholine and halothane (a technique now obsolete), and, at present, it is much less frequently encountered. MMR is clinically significant because it may complicate airway management and herald the onset of MH.⁸²

When administered to persons genetically predisposed to myotonia, succinylcholine may precipitate tonic muscular contractions, ranging from trismus (which may prevent orotracheal intubation) to severe generalized myoclonus and chest wall rigidity²⁸ (which may prevent ventilation). Because the myotonic contractions are independent of neural activity, they cannot be aborted by an NDNMB. Usually the contractions are self-limited, but occasionally they can be life-threatening if an airway cannot be established and hypoxemia ensues.

NONDEPOLARIZING NEUROMUSCULAR BLOCKERS

Pharmacology

Table 69–1 summarizes the pharmacology and toxicity of the NDNMBs.^{46,71,72,78} Whereas atracurium is composed of 10 different isomers, each having its unique pharmacokinetic and pharmacodynamic profile, cisatracurium contains only the 1R-cis and 1'R-cis isomers. Both atracurium and cisatracurium exhibit organ-independent elimination and are rapidly metabolized by spontaneous (nonenzymatic) temperature- and pH-dependent Hoffmann degradation and, to a lesser extent, by ester hydrolysis. The latter is catalyzed by nonspecific plasma esterases distinct from the PChE that hydrolyzes succinylcholine. In addition, significant drug metabolism or elimination occurs in the liver and kidney.³⁰

Toxicology

The most important toxic effects of the NDNMBs are accumulation of laudanosine and persistent weakness. In general, limiting the drug dose and monitoring the drug effect with a portable nerve stimulator reduce the incidence of prolonged weakness.

Laudanosine. Metabolism of atracurium and cisatracurium generates laudanosine, which crosses the blood–brain and placental barriers and may cause neuroexcitation but lacks any neuromuscular blocking activity.²⁵ Metabolism of each atracurium molecule generates one molecule of laudanosine.⁸⁰ Cisatracurium is an improvement over atracurium because it produces one-third as much laudanosine (and is three times more potent).^{34,51}

In the CNS, laudanosine has an inhibitory effect at the γ -aminobutyric acid, nACh, and opioid receptors. At high serum

concentrations in experimental animals, laudanosine causes dose-related neuroexcitation, myoclonic activity (>14 µg/mL), and generalized seizures^{14,34} (>17 µg/mL). In humans, the toxic serum laudanosine concentration is unknown, and seizures directly attributable to atracurium have not been observed even after prolonged infusion in the ICU.^{34,105} In ICU patients who received a 72-hour infusion of atracurium (1 mg/kg/h), the highest serum laudanosine concentrations (10–20 µg/mL) were observed in patients with an impaired glomerular filtration rate.⁶³ Laudanosine is excreted primarily in the bile, and its elimination is prolonged in patients with liver disease, biliary obstruction, and kidney disease.⁸⁶

Persistent Weakness Associated with Nondepolarizing Neuromuscular Blockers

Short-term blockade with a NDNMB usually resolves promptly upon discontinuation. When an NDNMB is administered for more than 48 hours, there is a risk that weakness will persist longer than anticipated based on the kinetics of drug elimination. In addition, critical illness is associated with dysfunction of the peripheral nerve, NMJ, and muscle (Table 69–4). For instance, in the ICU, persistent weakness is observed in 68% to 100% of patients with sepsis or multiple organ failure^{19,33,100} and in 20% to 30% of patients who receive NDNMB for only 48 to 72 hours.⁶⁵ Persistent weakness is multifactorial and associated with illness severity, sepsis, acute respiratory distress syndrome, multiorgan failure, hyperglycemia, NDNMBs; systemic corticosteroids, muscle injury, thermal injury, and electrolyte, endocrine, and nutritional disorders.^{18,23,43,64} Many xenobiotics given to patients in the ICU can cause weakness by themselves or potentiate the effects of NDNMBs.^{45,84} Progressive weakness and acute respiratory failure have even been described after discharge from the ICU and may be life threatening if not immediately recognized.⁵⁹ Patients who develop persistent weakness have a 2.5 to 3.5 fold increase in ICU mortality⁶⁵ and ICU stay.

TABLE 69–4. Acute Neuromuscular Pathology Associated with Critical Illness or Nondepolarizing Neuromuscular Blockers				
	Critical Illness Polyneuropathy	Residual Neuromuscular Block	Disease (Cachectic) Myopathy	Critical Illness Myopathy
Sensory	Moderate to severe, distal > proximal	Normal	Normal	Normal
Motor	Symmetric weakness, lower > upper extremity, proximal > distal or diffuse, respiratory failure	Diffuse symmetric weakness, respiratory failure	Diffuse weakness, proximal > distal	Symmetric weakness, proximal > distal or diffuse, respiratory failure
Creatine phosphokinase	Normal	Normal	Normal	Elevated in ≤50%
Electrodiagnostic studies (EMG, NCV)	Axonal degeneration of motor > sensory, reduced sensory and motor compound action potentials, normal NCV	Fatigue at NMJ assessed by fade on repetitive nerve stimulation	Normal EMG and NCV	Myopathic changes, muscle membrane inexcitability, normal NCV
Muscle biopsy	Denervation atrophy	Normal	Atrophy of type 2 fibers, no myosin loss, no necrosis	Atrophy of type 2 (fast-twitch) fibers, myosin loss, mild myonecrosis, no inflammatory infiltration

EMG = electromyography; NCV = nerve conduction velocity; NMJ = neuromuscular junction.

REVERSAL OF NEUROMUSCULAR BLOCKADE

Pharmacology

Termination of NMB effect initially results from drug redistribution and later from drug elimination, metabolism, or chemical antagonism. Pharmacologic antagonism of a partial NDNMB is achieved by giving a reversal agent that inhibits junctional AChE and increases ACh at the NMJ. This increase in ACh can overcome the competitive inhibition caused by a residual NDNMB. The commonly used anti-ChEs are polar molecules that possess a quaternary ammonium (Table 69–5). Neostigmine and pyridostigmine are hydrolyzed by ChE and form short-lived carbamyl complexes (half-life, 15–20 minutes) with the esteratic site of the enzyme.⁵ In contrast, edrophonium is not hydrolyzed by ChE; rather, it forms an electrostatic interaction and a hydrogen bond with the cationic site of ChE that is both competitive and reversible. Neostigmine and pyridostigmine, but not edrophonium, inhibit PChE and thus prolong the effects of xenobiotics metabolized by this enzyme, such as succinylcholine.³¹

TABLE 69–5. Pharmacology of Intravenous Neuromuscular Blockade Reversal Drugs and Coadministered Antimuscarinics

<i>Anticholinesterases</i>			
	<i>Neostigmine</i>	<i>Pyridostigmine</i>	<i>Edrophonium</i>
Initial dose (mg/kg)	0.04–0.08	0.2–0.4	0.5–1.0
Onset (minute)	7–11	10–16	1–2
Duration (minute)	60–120	60–120	60–120
Recommended antimuscarinic	Glycopyrrolate	Glycopyrrolate	Atropine
<i>Antimuscarinics</i>			
	<i>Glycopyrrolate</i>	<i>Atropine</i>	
Structure	Quaternary ammonium	Tertiary amine	
Initial dose (mg/kg)	0.01–0.02	0.02–0.03	
Onset (minute)	2–3	1	
Duration (minute)	30–60	30–60	
Elimination	Renal	Renal	
Crosses blood-brain barrier	No	Yes	

TOXICOLOGY OF REVERSAL AGENTS

The most common and troublesome clinical side effect of ChE inhibition is bradycardia, which usually is prevented by coadministration of an antimuscarinic.¹⁶ Bradydysrhythmias may be severe and lead to nodal or idioventricular rhythm, complete heart block, or even asystole.⁶⁶ These side effects occur more frequently in patients with preexisting bradycardia and those receiving chronic β -adrenergic antagonist therapy. They are not necessarily prevented by prior administration of atropine.⁹⁶ Other problems that may result from excess ChE inhibition are hypersalivation, lacrimation, bronchospasm, increased bronchial secretions, abdominal cramping from intestinal hyperperistalsis, cell division, and increased bladder tone. After general anesthesia, use of anti-ChE reversal agents may increase the incidence of nausea, vomiting, and abdominal cramps.⁵⁰ Because atropine crosses the blood–brain barrier, it may produce central anticholinergic syndrome.

DIAGNOSTIC TESTING

Quantitative methods for analysis of blood and tissue NDNMB and metabolite concentrations using high-performance liquid chromatography and mass spectrometry are described.^{49,94}

Succinylcholine and succinylmonocholine can be assayed by gas chromatography and mass spectrometry in blood, urine, or the site of intramuscular injection.^{81,95} Less than 3% of administered succinylcholine and 10% of its metabolite succinylmonocholine are excreted in the urine. However, both the parent drug and the metabolite undergo spontaneous hydrolysis, especially in alkaline conditions.⁹⁹ Historically, detection of succinylcholine has proven difficult because of its rapid hydrolysis. However, techniques for detecting this parent compound in tissues even after embalming are described.³⁷ Because succinic acid is also a product of normal intermediary metabolism, assay of this metabolite is not useful for positive identification of prior succinylcholine exposure.⁷⁴ Surprisingly, the presence of succinylmonocholine in forensic samples also cannot prove prior exposure to succinylcholine. Succinylmonocholine in concentrations of 0.01 to 0.20 $\mu\text{g/g}$ has been detected in tissues of six autopsy cases with no history of succinylcholine exposure.⁶¹

SUMMARY

- Succinylcholine is the only DNMB in current clinical use. Its immediate adverse effects include dose- and rate-related histamine release and modulation of autonomic tone.
- Acute and potentially fatal hyperkalemia may occur after succinylcholine administration, particularly in patients with certain myopathies (eg, Duchenne muscular dystrophy).

- In MH, acute onset of severe hypermetabolism, causing acidosis, rhabdomyolysis, hyperkalemia, and death occurs if treatment with dantrolene and aggressive cooling is not rapidly administered.
- The most important complications associated with use of NDNMBs are undetected hypoventilation and prolonged drug effect. NDNMBs have clinically important interactions with many xenobiotics and coexisting medical conditions.
- In most neuromuscular diseases, sensitivity to NDNMBs is increased. In renal failure, active metabolites of pancuronium and vecuronium may accumulate and cause prolonged block.

A21 ANTIDOTES IN DEPTH

Dantrolene Sodium

Kenneth M. Sutin

INTRODUCTION

Dantrolene produces relaxation of skeletal muscle without causing complete paralysis, and it is the only xenobiotic proven to be effective for both treatment and prophylaxis of malignant hyperthermia (MH).⁸ MH should be considered when hyperthermia is associated with severe hypermetabolism, increased CO₂ production, metabolic acidosis with elevated lactate, hyperkalemia, and rhabdomyolysis, especially when the course is fulminating and refractory to supportive therapy.

HISTORY

Dantrolene was first synthesized in 1967.²⁹ Four years later, the xenobiotic was first used clinically in oral form to treat skeletal muscular spasticity caused by neurologic disorders.⁶ The ability of intravenous (IV) dantrolene to rapidly reverse MH (muscle rigor, acidosis, and temperature rise) was first reported in swine in 1975¹¹ and in humans in 1982.¹⁶ The delay from dantrolene discovery to clinical use was in part due to the difficulty encountered in formulating a parenteral (water-soluble) solution of the lipid-soluble drug.

PHARMACOLOGY

Although dantrolene is a hydantoin derivative that is structurally similar to local anesthetics and anticonvulsants, it possesses none of their properties.^{17,33} The drug is highly lipophilic and relatively insoluble in water. It exhibits variable absorption by the small intestine. Oral bioavailability is up to 70%, and peak blood concentrations are achieved 3 to 6 hours after ingestion.¹⁷ Dantrolene is reversibly bound to plasma proteins, especially albumin.

Quantitative analysis of dantrolene and its metabolites has been performed using reverse phase, high-performance liquid chromatography.¹ After a 2.4 mg/kg IV dose, the mean serum dantrolene concentration is 4.2 µg/mL.⁸ This concentration produced a 75% reduction in twitch contraction of skeletal muscle.⁸ The therapeutic serum concentration in humans is estimated at 2.8 to 4.2 µg/mL.⁸

Pharmacokinetics are well described by a two-compartment model with an initial volume of distribution of 3.24 L and a secondary compartment volume of 22.4 L.²³ Most of the drug is eliminated by the liver; dantrolene is metabolized by 5-hydroxylation of the hydantoin ring or by reduction of the nitro group to an amine.³³ Up to 20% of administered dantrolene is excreted in the urine as the 5-hydroxydantrolene metabolite, which is half as potent as the parent drug.³³ In adults, the elimination half-life is 6 to 9 hours for dantrolene and 15.5 hours for the 5-hydroxydantrolene metabolite.³³ In one study of children aged 2 to 7 years, the dantrolene elimination half-life was 10 hours and that for 5-hydroxydantrolene was 9 hours.¹⁸

At therapeutic concentrations, dantrolene inhibits binding of [³H]ryanodine to the ryanodine receptor type 1 (RYR-1) on the sarcoplasmic reticulum membrane of skeletal muscle,²² causing a dose-dependent inhibition of both the steady state and peak concentrations of calcium release.³⁰ This reduces the free myoplasmic calcium, thereby directly inhibiting excitation-contraction coupling.¹⁹ Dantrolene causes skeletal muscle weakness but not complete paralysis, and this plateau effect may

be related to its low water solubility. This plateau effect (achieved at a serum concentration of 4.2 µg/mL) produces a 75% reduction of skeletal muscle twitch contraction and a 42% reduction in hand grip strength.⁸ Dantrolene does not change the electrical properties or excitation of nerve, excitation–contraction coupling at the neuromuscular junction, or skeletal muscle, and it does not alter sarcoplasmic calcium reuptake. Because dantrolene does not bind to the cardiac ryanodine receptor (RYR-2), it has minimal cardiac effects^{10,32,35} and no effect on smooth muscle.

ROLE IN MALIGNANT HYPERTHERMIA AND OTHER HYPERTHERMIAS

Dantrolene is indicated for treatment of skeletal muscle hypermetabolism characteristic of MH and, following an acute episode of MH, to prevent recrudescence. Long-term oral dantrolene therapy is used rarely to treat chronic spasticity.¹⁵ Historically, dantrolene was used prophylactically in MH-susceptible individuals; however, current practice is simply to avoid exposure to MH-triggering xenobiotics during anesthesia in potentially susceptible patients (Table 30–1). Dantrolene should be considered for patients with severe hypermetabolism when the diagnosis of MH cannot be excluded with certainty, especially when there is coexisting respiratory and metabolic acidosis, coagulopathy, hyperthermia, and rhabdomyolysis.⁷ In typical fulminant MH, the diagnosis is not subtle, and the course of treatment is obvious once the diagnosis is considered. This is not true when the clinical presentation is atypical. Atypical clinical presentations of MH in the presence or absence of triggering anesthetics are reported, especially in MH-susceptible individuals.

Dantrolene has been used to treat acute hyperthermia other than that caused by MH, including neuroleptic malignant syndrome,²⁴ heat stroke,² serotonin toxicity,¹² monoamine oxidase inhibitor overdose,¹³ methylenedioxymethamphetamine (“ecstasy”) overdose,^{20,26} intrathecal baclofen withdrawal,¹⁴ and thyroid storm.⁵ Given the lack of evidence-based support, dantrolene therapy is not recommended for indications other than MH. However, because (a) the differential diagnosis of a hyperthermic syndrome does not necessarily exclude (and often includes) MH, (b) the definitive diagnosis of a hyperthermic syndrome may be subtle or delayed, and (c) MH may occur simultaneously with another hyperthermic syndrome,²¹ consideration should be given to dantrolene therapy when MH cannot be specifically excluded; its use may be lifesaving. It bears emphasis that dantrolene given for hyperthermia is not a substitute for aggressive cooling.

ADVERSE EFFECTS AND SAFETY ISSUES

The alkaline pH of the reconstituted dantrolene causes venous irritation (pain) and thrombophlebitis with an incidence of 9%.³ Unintended extravasation can cause tissue necrosis, highlighting that dantrolene should only be given through a central vein or a large peripheral vein. There is no evidence to suggest allergic cross-reactivity with dantrolene in patients with prior phenytoin allergy.

When given to healthy persons or for MH prophylaxis or treatment, dantrolene causes skeletal muscle weakness (but not paralysis) in 15% to 22% of cases, as well as diaphragm weakness (dyspnea).^{3,34} In healthy volunteers, dantrolene 2.5 mg/kg does not reduce respiratory rate, vital capacity, or peak expiratory flow rate.⁸ However, in patients with diminished respiratory reserve (eg, end-stage pulmonary disease, preexisting neuromuscular disease), dantrolene may precipitate respiratory failure.^{3,17} Dantrolene may cause gastrointestinal upset, nausea, and vomiting. Other reported side effects include dizziness, somnolence, disorientation, ptosis, blurred vision, and difficulty swallowing.^{3,8,34} Uncommonly, compartment syndrome is observed and, even though likely secondary to MH or trauma, may be associated with dantrolene administration.³

Dantrolene and verapamil should not be used in combination because of the risk of hyperkalemia and hypotension; however, the mechanistic details of this drug interaction remain unclear.^{17,25,27} IV calcium salts are safe to administer with dantrolene if needed, such as for the treatment of cardiac dysrhythmias or hyperkalemia (during an episode of MH).

When dantrolene is given orally for more than 2 months to treat skeletal muscle spasticity, there is a 1.8% risk of dose- and duration-related chronic hepatitis, including elevated aminotransferase concentrations, hyperbilirubinemia, or jaundice³¹ that may not be fully reversible after dantrolene is discontinued.⁴

PREGNANCY AND LACTATION

Dosing during pregnancy is based on total body weight. Dantrolene crosses the placenta and is excreted in breast milk. When the maternal blood concentration achieved 0.99 µg/mL, the neonatal cord blood and serum concentration was 0.68 and 0.72 µg/mL, respectively.²⁸ The neonatal drug elimination half-life is about 20 hours.²⁸ Peak concentrations of dantrolene in breast milk 36 hours after maternal dantrolene 2.5 mg/kg given intravenously were 1.2 µg/mL, and the elimination half-life was 9 hours from breast milk.⁹ At the concentrations achieved in serum or breast milk, there are no reports of significant adverse effects on the neonate; however, it is suggested the breast feeding resume 48 hours after the last dose of dantrolene.⁹

DOSING AND ADMINISTRATION

The initial dose of dantrolene for treatment of acute MH is an IV bolus of 2 to 3 mg/kg in the adult and pediatric population.¹⁸ For a typical adult, 10 bottles of dantrolene are simultaneously reconstituted for the initial dose. Also, initial dosing probably should be determined by total body weight given that dantrolene is lipophilic; however, its pharmacokinetics in obesity are not determined.⁸ Redosing of 2 to 3 mg/kg IV is repeated every 15 minutes until the signs of hypermetabolism are reversed or until a total dose of approximately 10 mg/kg has been administered. Occasionally, however, doses in excess of 10 mg/kg have been required. The key point is that the total dose of dantrolene is determined by titration to a metabolic end point—resolution of skeletal muscle hypermetabolism. When an effective dose of dantrolene is given, signs of muscle hypermetabolism start to normalize usually within 30 minutes.¹⁶

Following successful termination of the acute episode of hypermetabolism, it is recommended that dantrolene therapy be continued 1 mg/kg IV every 6 hours for at least 24 hours to prevent recrudescence. Alternatively, a maintenance infusion can be started 5 hours after the initial dose (ID) according to the formula:

$$\text{Maintenance Infusion: (mg/kg/24 hours)} = \text{ID} \times 1.096$$

For example, if the ID of dantrolene is 5 mg/kg, it is continued as an infusion 5.48 mg/kg/24 h.²³

FORMULATION

Dantrolene is supplied as a sterile lyophilized powder in a 70 mL vial that contains 20 mg dantrolene sodium, 3 g mannitol (to maintain tonicity), and sodium hydroxide (to maintain a pH of 9.5 after reconstitution in 60 mL of sterile water). The dantrolene powder must be reconstituted in preservative-free sterile water for injection (and not 0.9% sodium chloride or dextrose-containing solutions) as this hastens dissolution and prevents precipitation. Prewarming the water to a maximum of 102°F (39°C) may decrease the time to dissolve the powder; this can be accomplished by storing sterile water in a warmed cabinet. There is, however, no evidence that prewarming improves clinical outcome, and the current formulation of Dantrium reconstitutes in about 20 seconds. After addition of 60 mL sterile water to each vial, the dantrolene bottles are shaken until the solution becomes clear (indicating the powder is fully dissolved). The final solution is isotonic and has pH of approximately 9.5. The extreme alkalinity of the reconstituted solution can corrode glass and thus must not be transferred into a glass bottle.

SUMMARY

- Dantrolene is the only specific antidote to treat malignant hyperthermia. The initial dose of dantrolene for treatment of acute MH is an IV bolus of 2 to 3 mg/kg in the adult and pediatric population, which is repeated every 15 minutes until clinical signs of hypermetabolism are corrected.
- The therapeutic serum concentration in humans is estimated at 2.8 to 4.2 µg/mL. Most of the drug is eliminated by the liver; it is metabolized by 5-hydroxylation of the hydantoin ring or by reduction of the nitro group to an active metabolite.
- Dantrolene is relatively lipophilic and crosses the placenta and is excreted in breast milk.
- MH Hotline: 800-644-9737.

G. PSYCHOTROPICS

CASE STUDY 5

History A 54 year-old man presented to the emergency department (ED) complaining that he was weak and dizzy and felt as if he was about to pass out. His past medical history was significant for opioid dependence. He recently saw an alternative medical provider and was given a natural remedy to help him detoxify. Prior to therapy, he was on daily methadone, but transitioned to hydrocodone in preparation for treatment. He was treated by his provider approximately 3 to 4 hours before presentation and sent to the ED because he was unwell. He denied nausea, vomiting, diarrhea, lacrimation, or other symptoms consistent with opioid withdrawal. In triage, his pulse was 35 beats/min, so the patient was rushed to the critical care area.

Immediate Assessment and Management On arrival to the critical care area he was awake but complaining of weakness. Vital signs were: blood pressure, 128/62 mm Hg; pulse, 35 beats/min, respiratory rate, 14 breaths/min; temperature, 98.4°F (36.9°C); oxygen saturation, 98% on room air; and glucose, 110 mg/dL. A general physical examination was unremarkable and specifically noted the absence of mydriasis, piloerection, rhinorrhea, or lacrimation. An electrocardiogram (ECG) was obtained (Fig. CS5–1), which was notable for sinus bradycardia with a QT interval of approximately 600 msec and an abnormally shaped T wave. Blood was sent for a complete blood count and electrolytes. The patient was attached to continuous cardiac monitoring.

FIGURE CS5–1. Initial electrocardiograph demonstrating sinus bradycardia at a heart rate of 35 beats/min with a normal axis, normal PR interval of 120 msec, a normal QRS duration of 80 msec, and prolonged QT interval at nearly 600 msec with an abnormal T-wave morphology.

Suddenly, the patient lost consciousness and became pulseless. A rhythm strip captured the event (Fig. CS5–2), which was determined to be torsade de pointes (TdP) (Chap. 16). The event was self-limited but recurred, at which time he was given 2 g of magnesium sulfate intravenously followed by a continuous magnesium infusion at 1 g/h. His cardiac rhythm returned to sinus, and he was moved to the cardiac intensive care unit (CCU) where a temporary transvenous pacemaker was inserted.

FIGURE CS5–2. Electrocardiograph associated with loss of consciousness demonstrating the transition from bradycardia to ventricular ectopy followed by a run of torsade de pointes.

What Is the Differential Diagnosis? In addition to congenital and acquired intrinsic cardiac conditions and electrolyte abnormalities ([Chap. 19](#)), numerous xenobiotics from diverse chemical classes are associated with QT interval prolongation and the risk of TdP. These xenobiotics, which typically share an ability to block myocardial potassium channels ([Chap. 16](#)), can be found throughout this text. Common classes of xenobiotics in which some members are associated with QT interval prolongation and some specific examples are listed in [Table CS5–1](#). Readers are referred to www.crediblemeds.com, a comprehensive Web site that stratifies pharmaceuticals by risk. It is noteworthy that many nonpharmaceutical xenobiotics also are listed in the table and text.

TABLE CS5–1. Xenobiotics Classes Associated with QT Interval Prolongation and Torsade de Pointes

Class/Chapter	Specific Examples
β-Adrenergic antagonists	Sotalol
Antibiotics	Macrolides and fluoroquinolones
Anticonvulsants	Carbamazepine
Antidysrhythmics	(Class IA, IC, and III antidysrhythmics)
Antimalarials	Chloroquine, mefloquine, halofantrine
Antipsychotics	Phenothiazines, citalopram
Caustics	Hydrofluoric acid
Cyclic antidepressants	Most
Drugs of abuse	Cocaine
Herbals	Ibogaine
Metals	Arsenic, barium, cesium
Opioids	Methadone
Pesticides	Organic phosphorus compounds

What Rapid Clinical and Laboratory Analyses Can Help Determine the Etiology and Guide Therapy for This Patient’s Presentation? Because the differential diagnosis is so extensive, broad laboratory testing is not advocated to determine the etiology in patients with unclear causes for QT interval prolongation. Instead, efforts should be directed at thorough history taking, as the cause may become evident. Patients should have routine electrolytes measured, because hypokalemia, hypocalcemia, and hypomagnesemia can all either be the primary cause of QT interval prolongation or be contributory when another etiology exists. Since these electrolyte abnormalities can be rapidly corrected in most circumstances, they represent easy and important interventions. When acute overdose is suspected, gastrointestinal decontamination can help limit drug absorption or enhance elimination ([Chap. 8](#)).

Further Diagnosis and Treatment Laboratory evaluation demonstrated normal concentrations of magnesium and calcium, but hypokalemia (2.5 mEq/L) was identified. The patient stated that he had received ibogaine therapy to treat his opioid dependence, and ibogaine is associated with both bradycardia and QT interval prolongation ([Chap. 45](#)). While in the CCU, he had several episodes of ventricular ectopy but no recurrent TdP. His hypokalemia was corrected with supplemental potassium, and an echocardiogram showed no signs of structural heart disease. Several days later he was discharged with a normal heart rate and mild QT interval prolongation (470 msec).

70 ANTIPSYCHOTICS

David Juurlink

HISTORY AND EPIDEMIOLOGY

The development of antipsychotic drugs changed the practice of psychiatry. Prior to the introduction of chlorpromazine in 1950, patients with schizophrenia were treated with nonspecific sedatives such as barbiturates and chloral hydrate. Highly agitated patients were housed in large mental institutions and often placed in physical restraints, and thousands underwent surgical disruption of the connections between the frontal cortices and other areas of the brain (leucotomy). By 1955, approximately 500,000 patients with psychotic disorders were hospitalized in the United States. The advent of antipsychotics in the 1950s revolutionized the care of these patients. These drugs, originally termed major tranquilizers and subsequently neuroleptics, dramatically reduced the characteristic hallucinations, delusions, thought disorders, and paranoia—the “positive” symptoms of schizophrenia.

Shortly after the introduction of these drugs, it became apparent that they caused significant toxicity following overdose, a common occurrence in patients with mental illness. Moreover, they were also associated with a host of adverse effects, principally involving the endocrine and nervous systems. The latter includes the extrapyramidal syndromes (EPS), a constellation of disorders that are relatively common, sometimes irreversible and occasionally life threatening.

The search for new drugs led to the development of multiple antipsychotics of several chemical classes. These drugs exhibited varying potencies and markedly different adverse effect profiles. The novel antipsychotic clozapine was first synthesized in 1959, but it did not enter widespread clinical use until the early 1970s. Clozapine was unusual because it conferred a relatively low risk of EPS, but also because it was often effective in patients who had not responded well to other xenobiotics. Moreover, unlike the other available xenobiotics, it often improved the “negative” symptoms of schizophrenia such as avolition, alogia, and social withdrawal—symptoms that, while often less outwardly apparent than the positive symptoms, result in significant disability. Reports of life-threatening agranulocytosis led to the withdrawal of clozapine from the market in 1974, although it was reintroduced in 1990.^{9,49} However, the unique therapeutic and pharmacologic properties of clozapine led to its characterization as an atypical antipsychotic, the forerunner and prototype of many other second-generation antipsychotics that have now largely supplanted the earlier xenobiotics.

Most antipsychotic toxicity occurs by one of two mechanisms. Following overdose, antipsychotic toxicity is dose dependent and reflects an extension of the effects of the drug on neurotransmitter systems and other biologic processes. The features of antipsychotic drug overdose are therefore generally predictable based upon an understanding of the pharmacology of the drug. Unpredictable (idiosyncratic) adverse reactions also occur in the context of routine therapeutic use. These toxicities result from individual susceptibility, are sometimes pharmacogenetic in nature, and are less reliably correlated with the dose. In both types of toxicity, the severity of illness can range from minor to life threatening, depending on a number of other factors, including concomitant drug exposures, comorbidity, and access to medical care.

The true incidence of antipsychotic overdose and adverse reactions is not known with certainty. Some patients may not seek medical attention, whereas others may be misdiagnosed. Even among those who seek medical attention and are correctly diagnosed, notification of poison centers or other adverse event reporting systems is discretionary and incomplete (Chap. 136). With these limitations in mind, a few observations can be made.

In 2011, poison control centers in the United States were contacted about more than 3.6 million potential toxic exposures.¹⁶ Antipsychotic exposures are reported together with sedative-hypnotics, but these collectively represented 168,416 exposures (6.13% of all exposures). The vast majority of poison center calls involving antipsychotics pertain to intentional overdoses in patients 20 years or older, most of whom have a good outcome. However, antipsychotics were associated with more fatalities than any other group ($n = 401$ deaths), and most exposures involved atypical antipsychotics. Importantly, poison center data underestimate the annual incidence of poisoning and mortality associated with antipsychotics and likely identify only a small minority of adverse drug reactions involving these drugs.

Although all antipsychotics can exhibit significant toxicity in overdose, a substantial body of clinical experience and some observational data suggest that the low potency, first-generation antipsychotics such as thioridazine, chlorpromazine, and mesoridazine are associated with greater toxicity than other antipsychotics.^{17,19} Inferences regarding the relative toxicity of the antipsychotics derived from administrative data should be extrapolated to individual patients with caution,^{17,40} but at least one well done retrospective cohort study supports the notion that thioridazine is associated with

greater cardiovascular toxicity than other antipsychotics.¹⁹

PHARMACOLOGY

Classification

Antipsychotics can be classified in several ways, according to their chemical structure, their receptor binding profiles, or as “typical” or “atypical” antipsychotics. [Table 70–1](#) outlines the taxonomy of some of the more commonly used antipsychotics. Classification by chemical structure was most useful prior to the 1970s, when phenothiazines and butyrophenones constituted most of the antipsychotics in clinical use. Currently, the number of different compounds and their structural heterogeneity renders this scheme of little utility to clinicians. It is worth noting, however, that the phenothiazine antipsychotics bear a high degree of structural similarity to the tricyclic antidepressants (TCAs) ([Fig. 70–1](#)) and share many of their manifestations in overdose. The phenothiazines can be further classified according to the nature of the substituent on the nitrogen atom at position 10 of the center ring as either aliphatic, piperazine, or piperidine compounds.

TABLE 70–1. Classification of Commonly Used Antipsychotics

Classification	Compound	Usual Daily Adult Dose (mg)	Volume of Distribution (L/kg)	Half-Life (Range, hours)	Protein Binding (%)	Active Metabolite	Lipophilicity (LogD)
Typical Antipsychotics							
Butyrophenones	Droperidol	1.25–30	2–3	2–10	85–90	N	2.85
	Haloperidol	1–20	18–30	14–41	90	Y	2.80
Diphenylbutylpiperidines	Pimozide	1–20	11–62	28–214	99	Y	3.74
Phenothiazines							
Aliphatic	Chlorpromazine	100–800	10–35	18–30	98	Y	3.01
	Methotrimeprazine	2–50	23–42	17–78	NR	Y	6.5
	Promazine	50–1000	30–40	8–12	98	N	—
	Promethazine	25–150	9–25	9–16	93	Y	2.73
Piperazine	Fluphenazine	0.5–20	220	13–58 ^a	99	NR	4.29
	Perphenazine	8–64	10–35	8–12	>90	NR	3.94
	Prochlorperazine	10–150	13–32	17–27	>90	NR	3.69
	Trifluoperazine	4–50	NR	7–18	>90	Y	4.04
Piperidine	Mesoridazine	100–400	3–6	2–9	98	Y	1.45
	Thioridazine	200–800	18	26–36	96	Y	3.60
	Pipotiazine	25–250 (monthly IM depot)	7.5	3–11	NR	N	–1.81
Thioxanthenes	Chlorprothixene	30–300	11–23	8–12	NR	NR	—
	Flupenthixol	3–6	7–8	7–36	NR	NR	—
	Thiothixene	5–30	NR	12–36	>90	NR	2.96
	Zuclopenthixol	20–100	10	20	NR	NR	–2.18
Atypical Antipsychotics							
Benzamides	Amisulpride	50–1200	5.8	12	16	N	–1.42
	Raclopride	3–6	1.5	12–24	NR	N	1.19
	Remoxipride	150–600	0.7	3–7	80	Y	2.1
	Sulpiride	200–1200	0.6–2.7	4–11	14–40	N	0.6
Benzepines							
Dibenzodiazepine	Clozapine	50–900	15–30	6–17	95	Y	3.40
Dibenzosazepine	Loxapine ^b	20–250	NR	2–8	90–99	Y	2.91
Thienobenzodiazepine	Olanzapine	5–20	10–20	21–54	93	N	3.20
Dibenzothiazepine	Quetiapine	150–750	10	3–9	83	N	1.82
Indoles							
Benzisoxazole	Risperidone	2–16	0.7–2.1	3–20	90	Y	1.88
	Paliperidone	1–12 mg (IM 25–150 monthly)	7	23	74	N	0.60
Imidazolidinone	Sertindole	12–24	20–40	24–200	99	Y	—
Benzothiazide	Ziprasidone	40–160	2	4–10	99	N	2.75
Quinolones	Aripiprazole	10–30	5	47–68	99	Y	5.55

^aThe atypical profile of loxapine is lost at doses >50 mg/d, it is sometimes therefore categorized as a typical antipsychotic. ^bFor hydrochloride salt, mesoridazine and decanoate have onsets of 3 to 4 days and 5 to 12 days, respectively.

NR = not reported.

Data from References 10, 12, 14, 37, 54, and 60.

FIGURE 70–1. Structural similarity between phenothiazines and cyclic antidepressants.

Of greater clinical utility is the classification of antipsychotics according to their binding affinities for various receptors ([Table 70–2](#)). However, by far the most widely used classification system categorizes antipsychotics as either typical or atypical. Typical (also called traditional, conventional or, increasingly, first-generation) antipsychotics dominated the first 40 years of antipsychotic therapy. They were subcategorized according to their affinity for the D₂ receptor as either low potency (exemplified by thioridazine and chlorpromazine) or high potency (exemplified by haloperidol). They ameliorated the positive symptoms of schizophrenia, such as hallucinations, delusions, paranoia, and disorganization of thought, but were of little benefit for the sometimes disabling negative symptoms including avolition, alogia, flattening of affect, and social withdrawal. Moreover, they were associated with acute, subacute, and long-term motor disturbances collectively referred to as EPS.

TABLE 70–2. Toxic Manifestations of Selected Antipsychotics

	<i>α</i> ₁ -Adrenergic Antagonism	Muscarinic Antagonism	Fast Sodium Channel (<i>I</i> _{Na}) Blockade	Delayed Rectifier (<i>I</i> _K) Current Blockade
Clinical effect	Hypotension	Central and peripheral anticholinergic effects	QRS widening; rightward T40msec; myocardial depression	QT interval prolongation; torsade de pointes
Typical Antipsychotics

Ziprasidone	++	-	-	+++

Data from References 18, 21, 45, 96, and 98.

The concept of antipsychotic atypicality has evolved over time with the introduction of new compounds^{94,113} and connotes different properties to pharmacologists and clinicians. From a clinical perspective, atypical antipsychotics (sometimes termed second-generation antipsychotics) treat both the positive and negative symptoms of schizophrenia, are less likely than traditional drugs to produce EPS at clinically effective doses, and cause little or no elevation of the serum prolactin concentration.⁵⁷ From a pharmacologic perspective, most atypical antipsychotics also inhibit the action of serotonin at the 5-HT_{2A} receptor. More than a dozen atypical antipsychotics are now in clinical use or under development. Despite their considerably higher cost, these drugs have largely supplanted traditional antipsychotics because of their effectiveness in treating the negative symptoms of schizophrenia and their somewhat more favorable adverse effect profile, in addition to the perception that they cause fewer long-term adverse effects than conventional antipsychotics—a belief that may result, in part, from the use of higher doses of older drugs in studies comparing the tolerability of typical and atypical antipsychotics.⁴⁸ Considerable controversy exists regarding the superiority of these drugs over those of the first-generation antipsychotics, and it is worth noting that the use of the newer antipsychotics for other indications is extremely common, including their use as adjunctive treatment for major depression, eating disorders, attention-deficit hyperactivity disorder, insomnia, posttraumatic stress disorder, personality disorders, and Tourette syndrome.⁶⁸ However, the most extensive off-label use of these drugs is for the management of agitation associated with cognitive impairment in the elderly.

Mechanisms of Antipsychotic Action

Of the many contemporary theories of schizophrenia, the most enduring has been the dopamine hypothesis.¹⁰⁷ First advanced in 1967 and supported by in vivo data,¹ this theory holds that the “positive symptoms” of schizophrenia (hallucinations, delusions, paranoia, and disorganization of thought) result from excessive dopaminergic signaling in the mesolimbic and mesocortical pathways.⁷³ This hypothesis was borne in part from the observation that hallucinations and delusions could be produced in otherwise normal individuals by drugs that increase dopaminergic transmission, such as cocaine and amphetamine, and that these effects could be blunted by dopamine antagonists.

There are at least five subtypes of dopamine receptors (D₁ through D₅), but schizophrenia principally involves excess signaling at the D₂ subtype,¹⁰⁷ and antagonism of D₂ neurotransmission is the sine qua non of antipsychotic activity. Antipsychotics have different potencies at this receptor, reflected by the dissociation constant (K_d), which in turn reflects release of the drug from the D₂ receptor. For example, the receptor releases clozapine and quetiapine more rapidly than it

does any other drugs.^{105,107}

Dopamine receptors are present in many other areas of the central nervous system (CNS), including the nigrostriatal pathway (substantia nigra, caudate, and putamen, which collectively govern the coordination of movement), tuberoinfundibular pathway, hypothalamus and pituitary, and area postrema of the brainstem, which contains the chemoreceptor trigger zone (CTZ). Antipsychotic-related blockade of D₂ neurotransmission in these areas is associated with many of the beneficial and adverse effects of these drugs. For example, D₂ antagonism in the CTZ alleviates nausea and vomiting, whereas blockade of hypothalamic D₂ receptors increases pituitary prolactin release, resulting in gynecomastia and galactorrhea. Blockade of nigrostriatal D₂ receptors underlies many of the movement disorders associated with antipsychotic therapy.^{119,132}

Antipsychotics interfere with signaling at other receptors to varying degrees, including muscarinic receptors, H₁ histamine receptors, and α -adrenergic receptors. The extent to which these receptors are blocked at therapeutic doses can be used to predict the adverse effect profile of each antipsychotic.²¹ For example, drugs that antagonize muscarinic receptors at clinically effective doses (most notably the aliphatic and piperidine phenothiazines as well as clozapine, loxapine, olanzapine, and quetiapine) often produce anticholinergic adverse effects during routine use and can produce pronounced anticholinergic manifestations following overdose (Table 70–2). Similarly, blockade of peripheral α_1 -adrenergic receptors by the aliphatic and piperidine phenothiazines, clozapine, risperidone, and others renders them more likely to cause postural hypotension during therapy and clinically important hypotension following overdose. In contrast, haloperidol overdose is not characterized by marked antimuscarinic effects or hypotension.

Several antipsychotics also block voltage-gated fast sodium channels (I_{Na}). Although this effect is of little consequence during therapy, in the setting of overdose this can slow cardiac conduction (phase 0 depolarization) and impair myocardial contractility. This effect, most notable with the phenothiazines, is both rate- and voltage-dependent, and is therefore more pronounced at faster heart rates and less negative transmembrane potentials.¹⁸ Blockade of the delayed rectifier potassium current (I_{Kr}) can produce prolongation of the QT interval, creating a substrate for development of torsade de pointes.⁷⁸ QT interval prolongation is sometimes evident during maintenance therapy, particularly in patients with previously unrecognized repolarization abnormalities or additional risk factors for QT prolongation. This effect may partially explain the dose-dependent increase in risk of sudden cardiac death among patients treated with typical and atypical antipsychotics.^{92,93}

Several antipsychotics exhibit a relatively high degree of antagonism at the 5-HT_{2A} receptor, which conveys two important therapeutic properties: (1) greater effectiveness for the treatment of the negative symptoms of schizophrenia and (2) a significantly lower incidence of extrapyramidal side effects. Others antipsychotics are distinguished by unique effects at different receptors. For example, loxapine and clozapine inhibit the presynaptic reuptake of catecholamines and antagonize γ -aminobutyric acid (GABA)_A receptors,¹¹² which may explain the apparent increase in seizure activity with these antipsychotics.⁸⁹ A more detailed description of the pharmacology of the most commonly used second-generation antipsychotics is warranted in light of their increasing role in therapy.

Clozapine, a dibenzodiazepine compound, binds to dopamine receptors (D₁–D₅) and serotonin receptors (5-HT_{1A/1C}, 5-HT_{2A/2C}, 5-HT₃, and 5-HT₆) with moderate to high affinity.^{9,90,98} It also antagonizes α_1 -adrenergic, α_2 -adrenergic, and H₁ histamine receptors. It has the highest binding affinity of any atypical antipsychotic at M₁ muscarinic receptors.⁹⁷ Despite this feature, clozapine paradoxically activates the M₄ subtype of the muscarinic receptor and frequently produces sialorrhea during therapy.⁹⁶

Olanzapine, a thienobenzodiazepine, binds avidly to serotonin (5-HT_{2A/2C}, 5-HT₃, and 5-HT₆) and dopamine receptors (D₁, D₂, and D₄), although its potency at D₂ receptors is lower than that of most traditional antipsychotics.^{60,98} It is an exceptionally potent H₁ antagonist, binding more avidly than pyrilamine, which is a widely used antihistamine. It is also has a high affinity for M₁ receptors and is a relatively weak α_1 antagonist.

Risperidone, a benisoxazole derivative, has high affinity for several receptors, including serotonin receptors (5-HT_{2A/2C}), D₂ dopamine receptors, and α_1 and H₁ receptors.^{60,96,98} It has no appreciable activity at M₁ receptors. Its primary metabolite (9-hydroxyrisperidone) is nearly equipotent as the parent compound at D₂ and 5-HT_{2A} receptors.⁶⁰ Available orally and as a long-acting parenteral preparation, paliperidone is the major active metabolite of risperidone and exhibits a similar receptor-binding profile.

Quetiapine, a dibenzothiazepine, is a weak antagonist at D₂, M₁, and 5-HT_{1A} receptors, but it is a potent antagonist of α_1 -adrenergic and H₁ receptors.⁶⁰ Of its 11 metabolites, at least 2 are pharmacologically active, but they circulate at low concentrations and likely contribute little to its clinical effect. A considerable proportion of fatalities involving antipsychotic drugs reported to North American Poison Control Centers involve quetiapine, usually in combination with other drugs.¹⁶

Ziprasidone, a benzothiazole derivative, is an antagonist at dopaminergic D₂ and several serotonin (5-HT_{2A/2C}, 5-HT_{1D}, and 5-HT₇) receptors, but it also displays agonist activity at 5-HT_{1A} receptors.^{60,61,98} Its α₁-antagonist activity is particularly strong, with a binding affinity approximately one tenth that of prazosin. In addition, it is a strong inhibitor of the delayed rectifier channel (I_{Kr}) and can significantly prolong repolarization.^{61,70}

Aripiprazole, a quinolinone derivative, is a novel compound that binds avidly to dopamine D₂ and D₃ receptors and serotonin 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{2B} receptors.^{77,98} Some evidence suggests that its efficacy in the treatment of schizophrenia and its lower propensity for EPS may relate to partial agonist activity at dopamine D₂ receptors.⁷⁶ Aripiprazole acts as a partial agonist at serotonin 5-HT_{1A} receptors but is an antagonist at serotonin 5-HT_{2A} receptors. Its principal active metabolite, dehydroaripiprazole, has affinity for dopamine D₂ receptors and thus has pharmacologic activity similar to that of the parent compound.⁷⁷

Like aripiprazole, bifeprunox is a partial agonist at D₂ and 5-HT_{1A} receptors. It has been characterized as a third-generation antipsychotic and has no appreciable affinity for serotonin 5-HT_{2A} and 5-HT_{2C} histaminergic or muscarinic receptors.^{28,80,106}

Amisulpride is a substituted benzamide derivative that preferentially blocks dopamine receptors in limbic rather than striatal structures. At low doses, it blocks presynaptic D₂ and D₃ receptors, thereby accentuating dopamine release, while at high doses it blocks postsynaptic D₂ and D₃ receptors. It has relatively low affinity for serotonergic, histaminergic, adrenergic, and cholinergic receptors.

Sertindole is a second-generation antipsychotic drug that was recently reintroduced into the market after being voluntarily withdrawn in 1998 over concerns about its effects on the QT interval. It binds to striatal D₂ receptors, although less avidly than olanzapine, and also exhibits antagonism at 5-HT_{2A} and α₁-adrenergic receptors.^{59,86,111} It is estimated that 3.1% to 7.8% of patients receiving sertindole develop QT intervals greater than 500 milliseconds.¹³⁰

PHARMACOKINETICS AND TOXICOKINETICS

With a few exceptions, the antipsychotics have similar pharmacokinetic characteristics regardless of their chemical classification. Most are lipophilic, have a large volume of distribution, and are generally well absorbed, although anticholinergic effects may delay absorption of some antipsychotics. Serum concentrations generally peak within 2 to 3 hours after a therapeutic dose, but this can be prolonged following overdose.

Most antipsychotics are substrates for the various isozymes of the hepatic cytochrome P450 (CYP) enzyme system. For example, haloperidol, perphenazine, thioridazine, sertindole, and risperidone are extensively metabolized by the CYP2D6 system, which is functionally absent in approximately 7% of white patients and overexpressed in 1% to 25% of patients, depending on ethnicity.⁵³ These polymorphisms appear to influence the tolerability and efficacy of treatment with these antipsychotics during therapeutic use^{15,29,30,56,124} but are unlikely to significantly alter the severity of acute antipsychotic overdose.

Drugs that inhibit CYP2D6 (such as paroxetine, fluoxetine, and bupropion) can increase the concentrations of these antipsychotics and increase the risk of adverse effects. In contrast, metabolism of clozapine is primarily mediated by CYP1A2, and increased clozapine concentrations can result following exposure to CYP1A2 inhibitors such as fluvoxamine, macrolide and fluoroquinolone antibiotics, as well as after smoking cessation, because smoking induces CYP1A2.³⁵ The kidney plays a relatively small role in the elimination of antipsychotics, and dose adjustment is generally not necessary for patients with kidney disease.

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

Table 70–3 lists the adverse effects of antipsychotics. Some of these effects develop primarily following overdose, but others can occur during the course of therapeutic use.

TABLE 70–3. Adverse Effects of Antipsychotics

Cardiovascular	Tachycardia
Clinical	Hypotension (orthostatic or resting)
Electrocardiographic	Myocardial depression
	QRS complex widening
	Right deviation of terminal 40 msec of QRS axis
	QT interval prolongation
	Torsade de pointes
	Nonspecific repolarization changes
Central nervous system	Somnolence, coma
	Respiratory depression, loss of airway reflexes
	Hyperthermia
	Seizures
	Extrapyramidal syndromes
	Central anticholinergic syndrome
Dermatologic	Impaired sweat production
	Cutaneous vasodilation
Endocrine	Amenorrhea, oligomenorrhea, or metrorrhagia
	Breast tenderness and galactorrhea
Gastrointestinal	Impaired peristalsis
	Dry mouth
Genitourinary	Urinary retention
	Ejaculatory dysfunction
	Priapism
Ophthalmic	Mydriasis or miosis; visual blurring

Adverse Effects During Therapeutic Use

The Extrapyramidal Syndromes. The EPS (Table 70–4) are a heterogeneous group of disorders that share the common feature of abnormal muscular activity. Among the typical antipsychotics, the incidence of EPS appears to be highest with the more potent antipsychotics such as haloperidol and flupentixol, and lower with less potent antipsychotics such as chlorpromazine and thioridazine. Atypical antipsychotics are associated with an even lower incidence of EPS. Although the physiologic mechanisms for this observation are not fully understood, several hypotheses have been put forth. In addition to the aforementioned antagonism of 5-HT_{2A} receptors, some atypical antipsychotics dissociate more rapidly from the D₂ receptor and incite a lower degree of nigrostriatal dopaminergic hypersensitivity during chronic use.^{57,58,71} However, it is important to note that EPS can occur during treatment with any antipsychotic drug, regardless of typicality or potency.

TABLE 70–4. The Extrapyramidal Syndromes

<i>Disorder</i>	<i>Time of Maximal Risk</i>	<i>Features</i>	<i>Postulated Mechanism</i>	<i>Possible Treatments</i>
Acute dystonia	Hours to a few days	Sustained, involuntary muscle contraction, torticollis, including blepharospasm, oculogyric crisis	Imbalance of dopaminergic/cholinergic transmission	Anticholinergics, benzodiazepines
Akathisia	Hours to days	Restlessness and unease, inability to sit still	Mesocortical D ₂ antagonism	Dose reduction, trial of alternate drug, propranolol, benzodiazepines, anticholinergics
Parkinsonism	Weeks	Bradykinesia, rigidity, shuffling gait, masklike facies, resting tremor	Postsynaptic striatal D ₂ antagonism	Dose reduction, anticholinergics, dopamine agonists
Neuroleptic malignant syndrome	2–10 days	Many (Table 70–5): altered mental status, motor symptoms, hyperthermia, autonomic instability, catatonia, mutism	D ₂ antagonism in striatum, hypothalamus, and mesocortex	Cooling, benzodiazepines, supportive care, consider dantrolene, bromocriptine, amantadine, or other direct-acting dopamine agonists
Tardive dyskinesia	3 months to years	Late onset involuntary choreiform movements, buccolinguo-masticatory movements	Excess dopaminergic activity	Recognize early and stop offending antipsychotic; addition of another antipsychotic; cholinergics

Data from References 88 and 119.

Acute dystonia. Acute dystonia is a movement disorder characterized by sustained involuntary muscle contractions, often involving the muscles of the head and neck, including the extraocular muscles and the tongue, but occasionally involving the extremities. These contractions are sometimes referred to as limited reactions, reflecting their transient nature rather than their severity. All the currently available antipsychotics are associated with the development of acute dystonic reactions.¹¹⁹ Spasmodic torticollis, facial grimacing, protrusion of the tongue, and oculogyric crisis are among the more common manifestations. Laryngeal dystonia is a rare but potentially life-threatening variant that is easily misdiagnosed because it can present with throat pain, dyspnea, stridor, and dysphonia rather than the more characteristic features of dystonia.³⁸

Acute dystonia typically develops within a few hours of starting of treatment but may be delayed for up to a few days. Left untreated, dystonia resolves slowly over several days once the offending antipsychotic is withdrawn. Risk factors for acute dystonia include male gender, young age (children are particularly susceptible), a previous episode of acute dystonia, and recent cocaine use.^{120,132} Although the reaction may appear dramatic and sometimes is mistaken for seizure activity, it is rarely life threatening. Of note, drugs other than antipsychotics can sometimes cause acute dystonia, particularly metoclopramide, antidepressants, some antimalarials, histamine H₂-receptor antagonists, anticonvulsants, and cocaine.¹²⁰

Treatment of acute dystonia. Acute dystonia is generally more distressing than serious, but rare cases compromise respiration, necessitating supplemental oxygen and, occasionally, assisted ventilation.^{38,120} The response to parenteral anticholinergics often is rapid and dramatic, and every effort should be made to administer benztropine as the first-line agent (2 mg intravenously {IV} or intramuscularly {IM} in adults, or 0.05 mg/kg in children). Often, diphenhydramine is more readily available and can be used instead (50 mg IV or IM in adults, or 1 mg/kg in children). Parenteral benzodiazepines such as lorazepam (0.05–0.10 mg/kg IV or IM) or diazepam (0.1 mg/kg IV) should be considered if patients do not respond to anticholinergics, but they may also be effective as initial therapy. It is important to recognize that because the elimination half-life of most anticholinergics is shorter than that of most antipsychotics, dystonia can recur, and administering additional doses of an anticholinergic may be necessary over the next 48 to 72 hours.²⁷ Patients in whom acute dystonia jeopardizes respiration should be observed for at least 12 to 24 hours after initial resolution.

Akathisia. Akathisia (from the Greek phrase “not to sit”) is characterized by a feeling of inner restlessness, anxiety, or sense of unease, often in conjunction with the objective finding of an inability to sit still. Patients with akathisia frequently appear uncomfortable or fidgety. They may rock back and forth while standing, or may repeatedly cross and uncross their legs while seated. Akathisia can be difficult to diagnose and is easily misinterpreted as a manifestation of the underlying psychiatric disorder rather than an adverse effect of therapy.

Akathisia is common and may be an important determinant of adherence to therapy. Like acute dystonia, akathisia tends to occur relatively early in the course of treatment and coincides with peak antipsychotic concentrations in serum.¹³² The incidence appears highest with typical, high-potency antipsychotics and lowest with atypical antipsychotics. Although most cases develop within days to weeks after initiation of treatment or an increase in dose, a delayed-onset (tardive) variant is also recognized.

The pathophysiology of akathisia is incompletely understood but appears to involve antagonism of postsynaptic D₂

receptors in the mesocortical pathways.^{71,119} Interestingly, a similar phenomenon is described in patients following the initiation of treatment with antidepressants, particularly the selective serotonin reuptake inhibitors (Chap. 75).^{8,67}

Treatment of akathisia. Akathisia can be difficult to treat. A reduction in the antipsychotic dose is sometimes helpful, as is substitution of another (generally atypical) antipsychotic. Treatment with lipophilic β -adrenergic antagonists such as propranolol may reduce the symptoms of akathisia, but little evidence supports their use.^{65,88} Benzodiazepines produce short-term relief, and anticholinergics such as benztropine or procyclidine may reduce manifestations of akathisia, but they are more likely to be effective for akathisia induced by antipsychotics with little or no intrinsic anticholinergic activity.^{20,66}

Parkinsonism. Antipsychotics can produce a parkinsonian syndrome characterized by rigidity, akinesia or bradykinesia, and postural instability. It is similar to the idiopathic Parkinson disease, although the classic “pill-rolling” tremor is often less pronounced.⁸⁸ The syndrome typically develops during the first few months of therapy, particularly with high-potency antipsychotics. It is more common among older women, and in some patients it may represent iatrogenic unmasking of latent Parkinson disease. Parkinsonism is thought to result from antagonism of postsynaptic D_2 receptors in the striatum.¹¹⁹

Treatment of drug-induced parkinsonism. The risk of drug-induced parkinsonism can be minimized by using the lowest effective dose of antipsychotic. The addition of an anticholinergic often attenuates symptoms, at the expense of additional side effects. This strategy often is effective in younger patients, although the routine use of prophylactic anticholinergics is not recommended. Addition of a dopamine agonist such as amantadine is sometimes used, particularly in older patients who may be less tolerant of anticholinergics, but this may aggravate the underlying psychiatric disturbance.⁶⁹

Tardive dyskinesias. The term tardive dyskinesia was coined in 1952 to describe the delayed onset of persistent orobuccal masticatory movements occurring in three women after several months of antipsychotic therapy.¹¹⁹ The adjective tardive, meaning delayed, was used to distinguish these movement disorders from the Parkinsonian movements described above. The incidence of tardive dyskinesia in younger patients is approximately 3% to 5% per year but rises considerably with age. A prospective study of older patients treated with high potency typical antipsychotics identified a 60% cumulative incidence of tardive dyskinesia after 3 years of treatment.⁵³ Potential risk factors for tardive dyskinesia include alcohol use, affective disorder, prior electroconvulsive therapy, diabetes mellitus, and various genetic factors.¹¹⁹

Several distinct tardive syndromes are recognized, including the classic orobuccal lingual masticatory stereotypy, chorea, dystonia, myoclonus, blepharospasm, and tics. It is generally accepted that the atypical antipsychotics are associated with a lower incidence of tardive dyskinesia and other drug-related movement disorders. However, whether this is true of all atypical antipsychotics is unclear. Among the atypical antipsychotics, clozapine is associated with the lowest incidence of tardive dyskinesia and risperidone with the highest incidence (when higher doses are used), but the reasons for this observation are uncertain.^{115,116,119}

Treatment of tardive dyskinesia. Tardive dyskinesia is highly resistant to the usual pharmacologic treatments for movement disorders. Anticholinergics do not alleviate tardive dyskinesia and indeed may worsen it. Calcium channel blockers, β -adrenergic antagonists, benzodiazepines, and vitamin E have all been used with limited success.³⁶ Clozapine appears to suppress tardive dyskinesia temporarily. Although discontinuation of the causative antipsychotic may not produce total relief of symptoms, when possible, the antipsychotic should be discontinued as soon as signs or symptoms begin.

Neuroleptic malignant syndrome. Neuroleptic malignant syndrome (NMS) is a potentially life-threatening drug-induced emergency. First described in 1960 in patients treated with haloperidol, this syndrome has been associated with virtually every antipsychotic.³² The reported incidence of NMS ranges from 0.2% to 1.4% of patients receiving antipsychotics,^{2,23,114} but less severe episodes may go undiagnosed or unreported. As a result, much of what is known about the epidemiology and treatment of NMS is speculative and based upon case reports and case series.

The pathophysiology of NMS is incompletely understood but appears to involve abrupt reductions in central dopaminergic neurotransmission in the striatum and hypothalamus, altering the core temperature setpoint,⁴³ and leading to impaired thermoregulation and other manifestations of autonomic dysfunction. Blockade of striatal D_2 receptors contributes to muscle rigidity and tremor.^{13,25,121} In some cases, a direct effect on skeletal muscle may play a role in the pathogenesis of hyperthermia.⁴³ Altered mental status is multifactorial and may reflect hypothalamic and spinal dopamine receptor antagonism, a genetic predisposition, or the direct effects of hyperthermia and other drugs.⁴⁴ Serotonin also appears to play a role in the pathogenesis of NMS, because antipsychotics that antagonize 5-HT_{2A} receptors seem to be associated with a lower incidence of NMS.⁴

Although NMS most often occurs during treatment with a D_2 receptor antagonist, withdrawal of dopamine agonists can produce an indistinguishable syndrome. The latter typically occurs in patients with long-standing Parkinson disease who abruptly change or discontinue treatment with dopamine agonists such as levodopa/carbidopa, amantadine, or bromocriptine.¹³ The resulting disorder is sometimes referred to as the parkinsonian-hyperpyrexia syndrome, and mortality rates of up to 4% are reported.⁷⁹ Hospitalization for aspiration pneumonia, a common occurrence in older patients with Parkinson disease, is a particularly high-risk setting for this complication, and is particularly dangerous because the

cardinal manifestations of NMS are easily misattributed to the combined effects of pneumonia and the underlying movement disorder.

The vast majority of NMS cases occur in the context of therapeutic use of antipsychotics rather than following overdose. Postulated risk factors for the development of NMS include young age, male gender, extracellular fluid volume contraction, use of high-potency antipsychotics, depot preparations, cotreatment with lithium, multiple drugs in combination, and rapid dose escalation.^{2,24,63,81} One large observational study⁸¹ suggests that treatment with high-potency first-generation antipsychotics is associated with a more than 20-fold increase in the risk of NMS, although this may partly reflect heightened suspicion of the disorder in patients receiving those antipsychotics. The mortality rate of NMS associated with first-generation antipsychotics is estimated at approximately 16%, whereas the rate associated with second-generation antipsychotics is estimated at 3%.¹¹⁸

The manifestations of NMS include the tetrad of altered mental status, muscular rigidity (classically described as “lead pipe”), hyperthermia, and autonomic dysfunction. These symptoms can appear in any sequence, although a review of 340 NMS cases found that mental status changes and rigidity usually preceded the development of hyperthermia and autonomic instability.¹²² Occasionally, rigidity is not present when creatine kinase concentrations are elevated but emerges thereafter.⁸² Signs typically evolve over a period of several days, with the majority occurring within 2 weeks of initiation. However, it is important to recognize that NMS can occur even after prolonged use of an antipsychotic, particularly following a dose increase, the addition of another agent, or the development of intercurrent illness. It is also worth noting that the clinical course of NMS can fluctuate rapidly, sometimes waxing and waning dramatically over a few hours.

There is no universally accepted set of criteria for the diagnosis of NMS, and more than a dozen sets of criteria have been proposed.^{3,23,34,63} The operating characteristics of these criteria have not been formally evaluated, in part because of the absence of a gold standard. An international group has published the results of a Delphi consensus panel regarding the diagnosis of NMS.⁴² While these too have not yet been validated, the criteria and their relative importance are shown in Table 70–5.

TABLE 70–5. Suggested Diagnostic Criteria for the Neuroleptic Malignant Syndrome⁴³

<i>Criterion</i>	<i>Priority Score^a</i>
Exposure to a dopamine antagonist or withdrawal of a dopamine agonist in previous 72 hours	20
Hyperthermia (>100.4°F [38.0°C]) on at least two occasions, measured orally	18
Rigidity	17
Mental status alteration (reduced or fluctuating level of consciousness)	13
Creatine kinase elevation (at least four times the upper limit of normal)	10
Sympathetic nervous system lability, defined as at least two of: Blood pressure elevation (SBP or DBP ≥ 25% above baseline) Blood pressure fluctuation (≥ 20% DBP change or ≥ 25% SBP change in 24 hours) Diaphoresis Urinary incontinence	10
Hypermetabolic state (defined as heart rate increase ≥25% above baseline and respiratory rate increase ≥50% above baseline)	5
Negative workup for other toxic, metabolic, infectious, or neurologic causes	7

^aPriority scores sum to 100 and represent the perceived importance of eight criteria (distilled using a Delphi process from 64 distinct diagnostic features) relative to others. For example, a characteristic drug exposure history (20 points) is deemed approximately two times as important as creatine kinase elevation (10 points) and four times as important as the presence of a hypermetabolic state (5 points). Scores are not meant to be added, and no threshold is defined.

DBP = diastolic blood pressure; SBP = systolic blood pressure.

Reproduced with permission from Gurrera RJ1, Caroff SN, Cohen A, et al: An international consensus study of neuroleptic malignant syndrome diagnostic criteria using the Delphi method, *J Clin Psychiatry*. 2011;72:1222–1228.

It may be difficult to distinguish NMS from other toxin-induced hyperthermia syndromes, such as the anticholinergic (antimuscarinic) syndrome ([Chap. 49](#)) and serotonin toxicity ([Chap. 75](#)), all of which share the common features of elevated temperature, altered mental status, and neuromuscular abnormalities. The most important differentiating feature is the medication history, with dopamine antagonists, antimuscarinics, and direct or indirect serotonin agonists (often in combination) as the most likely causal agents, respectively. The time course of the illness may also help differentiate among the disorders. Serotonin toxicity and the antimuscarinic syndrome tend to develop rapidly after exposure to causative substances, while NMS typically develops more gradually, often waxing and waning over several days or more. Occasionally, clinicians must attempt to differentiate NMS from these disorders in the absence of a reliable medication history. The physical examination can be of some utility in this regard.⁸⁷ While NMS is classically characterized by rigidity, the presence of ocular or generalized clonus is more suggestive of serotonin toxicity, particularly when accompanied by shivering and hyperreflexia, features that are not typical of NMS. Because skeletal muscle contraction is effected by nicotinic rather than muscarinic transmission, patients with antimuscarinic syndrome have few muscular abnormalities. However, such patients can sometimes be resistant to physical restraint, giving the appearance of increased muscle tone.

Treatment of neuroleptic malignant syndrome: General measures. Treatment recommendations are largely based on general physiologic principles, case reports, and case series. Therapy should be individualized according to the severity and duration of illness and the modifying influences of comorbidity.^{13,95,123} The provision of good supportive care is the cornerstone for treatment of NMS. It is essential to recognize the condition as an emergency and to withdraw the offending antipsychotic immediately. When NMS ensues after abrupt discontinuation of a dopamine agonist such as levodopa, the drug should be reinstituted promptly. Most patients with NMS should be admitted to an intensive care unit. Supplemental oxygen should be administered, and assisted ventilation may be necessary in cases of respiratory failure, which can result from central hypoventilation, loss of protective airway reflexes, or rigidity of the chest wall muscles.

The hyperthermia associated with NMS is multifactorial in origin and, when present, warrants aggressive treatment. Submersion in an ice-water bath is rapidly effective, although this may be impractical in some settings ([Chap. 30](#)). Other strategies include the use of active cooling blankets, the placement of ice packs in the groin and axillae, or evaporative cooling, which can be accomplished by removing the patient's clothing and exposing the patient to cooled water or towels immersed in ice water, while maintaining constant air circulation with the use of fans.¹²⁷

Hypotension should be treated initially with generous volumes of isotonic crystalloid, followed by vasopressors if necessary. Alkalinization of the urine with sodium bicarbonate may reduce the incidence of myoglobinuric acute kidney injury (AKI) in patients with high creatine kinase concentrations, but maintenance of intravascular volume and adequate renal perfusion are of far greater importance. Tachycardia does not require specific treatment, but bradycardia may necessitate the use of transcutaneous or transvenous electrical pacing. Venous thromboembolism is a major cause of morbidity and mortality in patients with NMS, and prophylactic doses of low-molecular-weight heparin should be considered in patients who likely will be immobilized for more than 12 to 24 hours.

Treatment of neuroleptic malignant syndrome: Pharmacologic measures. Benzodiazepines are the most widely used pharmacologic adjuncts for treatment of NMS and are considered first-line therapy. Dantrolene and bromocriptine are not well studied, and their incremental benefit over good supportive care is debated.^{95,100} However, these drugs are associated with relatively little toxicity, and their use is therefore easily justified, particularly in patients with moderate or severe NMS.

Benzodiazepines are frequently used in the management of NMS because of their rapid onset of action, which is particularly important when patients are agitated or restless. They attenuate the sympathetic hyperactivity that characterizes NMS by facilitating GABA-mediated chloride transport and producing neuronal hyperpolarization, in a fashion analogous to their beneficial effects in cocaine toxicity.⁴⁴ The primary disadvantage of benzodiazepines is that they may cloud the assessment of mental status.

Dantrolene reduces skeletal muscle activity by inhibiting ryanodine receptor calcium release channels, interfering with calcium release from the sarcoplasmic reticulum. In theory, this process should reduce body temperature and total oxygen consumption. It also should lessen the risk of myoglobinuric AKI. Dantrolene has been suggested to be particularly useful when muscular rigidity is a prominent feature of NMS.¹³ It can be given by mouth (50–100 mg/d) or by IV infusion (2–3 mg/kg/d, or up to 10 mg/kg/d in severe cases), although the latter requires laborious reconstitution. A review of 271 published cases of NMS that included information regarding drug treatment found that combination therapy including dantrolene was associated with a prolonged clinical recovery, but also that dantrolene monotherapy was associated with higher mortality than other treatment modalities including supportive care.⁹⁵ The authors concluded that dantrolene was not an evidence-based therapy. However, it is also a relatively nontoxic drug that remains a reasonable therapeutic option in patients with NMS, particularly those with prominent and refractory rigidity.

Bromocriptine is a centrally acting dopamine agonist that is given orally or by nasogastric tube at doses of 2.5 to 10 mg, 3 to 4 times daily. The rationale for its use rests in the belief that reversal of antipsychotic-related striatal D₂ antagonism will ameliorate the manifestations of NMS. Other dopamine agonists anecdotally associated with success include

ropinirole, levodopa,^{84,110} and amantadine.^{41,52,114} When these drugs are used, they should be tapered slowly after the patient improves to minimize the likelihood of recrudescence NMS. In severe cases, dantrolene and a dopamine agonist can be used in combination. Of note, dopaminergic agents may be associated with exacerbation of underlying psychiatric illness.

Electroconvulsive therapy. Electroconvulsive therapy (ECT) has been reported to dramatically improve the manifestations of NMS, presumably by enhancing central dopaminergic transmission. In one report, five patients received an average of 10 ECT treatments, and resolution generally occurred after the third or fourth session.⁸³ Whether this result represents a true effect of ECT or simply the natural course of NMS with good supportive care alone is not clear. As with drug therapies for NMS, the efficacy of ECT remains unclear and its indications speculative, but its use seems reasonable in patients with severe, persistent, or treatment-resistant NMS and for those with residual catatonia or psychosis following resolution of other manifestations.^{13,84}

Adverse Effects on Other Organ Systems. Sedation, dry mouth, and urinary retention occur commonly with antipsychotics, particularly during the initial period of therapy. These symptoms occur most commonly with drugs having potent antihistaminic and antimuscarinic activity. All antipsychotics can lower the seizure threshold, but seizures are uncommon during therapeutic use. Because hypothalamic dopamine inhibits pituitary prolactin release, hyperprolactinemia and galactorrhea can occur. All antipsychotics are associated with metabolic derangements, including weight gain, dyslipidemia, and steatohepatitis. The metabolic syndrome appears most commonly in association with clozapine, olanzapine, and chlorpromazine.³¹ Rare but dramatic instances of glucose intolerance, including fatal cases of diabetic ketoacidosis, are also described.^{6,47,91,117} The mechanism of this is incompletely understood, but it is not adequately explained by the weight gain associated with antipsychotic therapy, because glucose disturbances often develop shortly after therapy is instituted. Other idiosyncratic reactions reported with use of antipsychotics include photosensitivity, skin pigmentation, and cholestatic hepatitis (particularly with the phenothiazines), myocarditis, and agranulocytosis, which occurs with many antipsychotic drugs, most notably clozapine (in up to 2% of patients).⁷⁵ Most of these conditions result from an immunologically based hypersensitivity reaction and develop during the first month of therapy. Finally, an increasing number of reports associate antipsychotics with venous thromboembolism.^{46,55} This may partially explain the high incidence of thromboembolic disease found in patients with NMS (see above).

Acute Overdose

Antipsychotic overdose can produce a spectrum of toxic manifestations affecting multiple organ systems, but most serious toxicity involves the CNS and cardiovascular systems. Some of these manifestations are present to a minor degree during therapeutic use, although they tend to be most pronounced during the early period of therapy and dissipate with continued use.

Impaired consciousness is a common and dose-dependent feature of antipsychotic overdose, ranging from somnolence to coma. It may be associated with impaired airway reflexes, but significant respiratory depression is uncommon. Many antipsychotics, including several of the atypical drugs, are potent muscarinic antagonists and can produce anticholinergic features in overdose.^{11,21,26} Peripheral manifestations include tachycardia, decreased production of sweat and saliva, flushed skin, urinary retention, diminished bowel sounds and mydriasis, although miosis also occurs. These findings may be present in isolation or coexist with central manifestations, including agitation, delirium, psychosis, hallucinations, and coma, some of which may be mistakenly attributed to the underlying psychiatric illness.

Mild elevations in body temperature are common and reflect impaired heat dissipation as a result of impaired sweating, and increased heat production in agitated patients. Hyperthermia should always prompt a search for other features of NMS. Tachycardia is a common finding in patients with antipsychotic overdose and reflects reduced vagal tone and, when present, a compensatory response to hypotension. Bradycardia is distinctly uncommon, and while it may be a preterminal finding, its presence should prompt a search for alternate causes including an ingestion of negative chronotropic drugs such as β -adrenergic antagonists, calcium channel blockers, cardiac glycosides, and opioids. Hypotension is a common feature of antipsychotic overdose and is generally due to peripheral α_1 -adrenergic blockade and decreased myocardial contractility.

The electrocardiographic (ECG) manifestations of antipsychotic overdose exhibit similarities to those of cyclic antidepressant toxicity (Chaps. 16 and 71) and include widening of the QRS complex and a rightward deflection of the terminal 40 msec of the QRS complex, typically manifesting as a tall, broad terminal component of the QRS complex in lead aVR. These changes reflect blockade of the inward sodium current (I_{Na}). Prolongation of the QT interval results from blockade of the delayed rectifier potassium current (I_{Kr}), creating a substrate for development of torsade de pointes.⁷⁸ This situation is sometimes evident during maintenance therapy and may underlie the apparent increase in sudden cardiac death among users of antipsychotics.^{92,93} A published meta-analysis of the operating characteristics of the ECG in patients with cyclic antidepressant toxicity found the ECG was a relatively poor predictor of seizures, dysrhythmia, and death.⁷ However, the ECG is a dynamic instrument, particularly in the initial hours following overdose, and few studies have

evaluated longitudinal changes in the ECG.⁶⁴

DIAGNOSTIC TESTS

The diagnosis of antipsychotic poisoning is supported by the clinical history, the physical examination, and a limited number of adjunctive tests. Both the clinical and ECG findings are nonspecific and can occur following overdose of several different drug classes, including CAs, skeletal muscle relaxants, carbamazepine, and first-generation antihistamines such as diphenhydramine. Moreover, the absence of typical ECG changes does not exclude a significant antipsychotic ingestion, particularly in the initial phase of an overdose, and at least one additional ECG should be performed in the subsequent 2 to 3 hours.

Abdominal radiography may reveal radioopacities in the gastrointestinal tract, as some solid dosage forms of phenothiazines are radiopaque. However, these tests are neither sensitive nor specific, and they are not routinely recommended.

Serum concentrations of antipsychotics are not widely available, do not correlate well with clinical signs and symptoms, and do not help guide therapy. Comprehensive urine drug screens using high-performance liquid chromatography, gas chromatography–mass spectrometry, or tandem mass spectrometry may indicate the presence of antipsychotics, but these tests are available at only a few hospitals and in most instances provide only a qualitative result. Blood and urine immunoassays for CAs may yield a false-positive result in the presence of phenothiazines.^{5,99}

MANAGEMENT

The care of a patient with an antipsychotic overdose should proceed with the recognition that other drugs, particularly other psychotropics, may have been coingested and can confound both the clinical presentation and management. Regularly encountered coingestants include other psychotropic drugs such as antidepressants, sedative-hypnotics, anticholinergics, valproic acid, and lithium, as well as ethanol and nonprescription analgesics such as acetaminophen and aspirin.

Supportive care is the cornerstone of treatment for patients with antipsychotic overdose. Supplemental oxygen should be administered if hypoxia is present. Patients with altered mental status should receive thiamine and naloxone, along with parenteral dextrose if hypoglycemia present. Intubation and ventilation are rarely required for patients with single drug ingestions but may be necessary for patients with very large overdoses of antipsychotics or ingestion of other CNS depressants. All symptomatic patients should undergo continuous cardiac monitoring. In addition, an ECG should be recorded upon presentation and reliable venous access obtained. Asymptomatic patients with a normal ECG obtained 6 hours after overdose are at exceedingly low risk of complications and no longer require cardiac monitoring. Symptomatic patients and those with an abnormal ECG should have continuous monitoring for a minimum of 24 hours.

Gastrointestinal Decontamination

Gastrointestinal decontamination with activated charcoal (1 g/kg by mouth or nasogastric tube) should be considered for patients who present within a few hours of a large or multidrug overdose. Although this intervention is time sensitive, many antipsychotics exhibit significant antimuscarinic activity and slow gastric emptying, thereby increasing the likelihood that activated charcoal will be beneficial. Although it is unknown whether activated charcoal improves clinically important outcomes, a Bayesian analysis of pharmacokinetic data from a series of quetiapine overdoses concluded that activated charcoal use led to a 35% reduction in the fraction of quetiapine absorbed.⁵⁰ Orogastric lavage and whole-bowel irrigation likely will not improve clinical outcomes and should not be routinely employed in the management of antipsychotic overdose.

Treatment of Cardiovascular Complications

Vital signs should be monitored closely. Hypotension may result from peripheral α -adrenergic blockade and is most likely to occur with older, low potency antipsychotics such as thioridazine.⁷⁶ The hypotension should be treated initially with appropriate titration of 0.9% sodium chloride solution (30–40 mL/kg). If vasopressors are required, direct-acting agonists such as norepinephrine or phenylephrine are preferred over dopamine, which is an indirect agonist and likely will be ineffective. Vasopressin or its analogs may also be used, although direct-acting vasopressors should be used with great caution in patients who have coingested a negative inotropic drug such as a β -adrenergic antagonist or calcium channel blocker. Continuous blood pressure monitoring may be warranted in such cases.

Progressive widening of the QRS complex is uncommon and reflects sodium channel blockade and slowing of phase 0 depolarization in the His-Purkinje system. This may be associated with reduced cardiac output and malignant ventricular dysrhythmias. Much of what is known about the treatment of sodium channel blocker toxicity derives from the cyclic antidepressant literature. Treatment recommendations are extended to sodium-channel-blocking antipsychotic drugs by analogy. Sodium bicarbonate (1–2 mEq/kg) is the first-line therapy for ventricular dysrhythmias and should be considered

for patients with dysrhythmias or QRS widening >0.12 msec. The rationale for this strategy is based upon the treatment of cyclic antidepressant overdose (Antidotes in Depth: A5). At least two mechanisms underlie the beneficial effects of sodium bicarbonate. First, the degree of sodium channel blockade is partially overcome by an increase in extracellular sodium. Indeed, hypertonic saline alone may be beneficial. Second, the binding of these drugs to the sodium channel is pH dependent, with less extensive binding at higher pH.

Repeated boluses of bicarbonate can be given to achieve a target blood pH of 7.5, although many toxicologists recommend continuous infusions.¹⁰⁹ If the patient is intubated, hyperventilation also can be used but is not comparably efficacious. If significant conduction abnormalities or ventricular dysrhythmias persist despite the use of sodium bicarbonate, lidocaine (1–2 mg/kg followed by continuous infusion) is a reasonable second-line antidysrhythmic. Although lidocaine is also a sodium channel antagonist, it exhibits rapid on/off sodium channel binding with preferential binding in the inactivated state and may lessen the cardiotoxicity associated with antipsychotic drug overdose.¹⁰⁸ Class IA antidysrhythmics (procainamide, disopyramide, and quinidine), class IC antidysrhythmics (propafenone, encainide, and flecainide), and class III antidysrhythmics (amiodarone, sotalol and bretylium) can aggravate cardiotoxicity and should not be used. When administering sodium bicarbonate to patients with antipsychotic overdose, caution must be taken to avoid hypokalemia, as many of these antipsychotics block cardiac potassium channels thereby prolonging the QT interval. Hypokalemia can exacerbate this blockade, potentially leading to torsade de pointes, particularly in overdoses involving amisulpride or ziprasidone.

Sinus tachycardia related to anticholinergic activity should not be treated unless it is associated with active ischemia, which, although uncommon, may complicate antipsychotic overdose in patients with existing coronary disease. Should symptomatic sinus tachycardia occur, a short-acting β -adrenergic antagonist such as esmolol may be preferable. Prolongation of the QT interval requires no specific treatment other than monitoring and correction of potential contributing causes such as hypokalemia and hypomagnesemia. Torsade de pointes should be treated with cardioversion followed by IV magnesium sulfate, taking care to prevent hypotension, which is dose- and rate-dependent. Overdrive pacing with isoproterenol or transcutaneous or transvenous pacing should be considered if the patient does not respond to magnesium sulfate, although in theory this therapy may worsen the rate-dependent sodium channel blockade.

Many antipsychotics, including olanzapine, quetiapine, and sertindole, exhibit a high degree of lipophilicity in addition to significant cardiovascular toxicity. Recently, considerable enthusiasm has emerged for the use of high-dose intravenous fat emulsion therapy for patients with significant overdoses of drugs displaying these characteristics. The rationale for this therapy rests, in part, in the concept that highly lipophilic drugs will selectively partition into the exogenous fat, thereby minimizing toxicity at the biophase. This treatment has been extensively studied in animal models of bupivacaine toxicity,^{33,125,126} but published experience with antipsychotics is limited to a handful of case reports.^{39,72,133} Dosing for fat “rescue” is not well established, but a popular protocol involves 20% lipid emulsion given as a bolus (1.5 mL/kg) followed by an infusion of 0.25 mL/kg/min for 30 to 60 minutes, with adjustment of therapy according to the individual response (Antidotes in Depth: A20). Extracorporeal circulatory support has been associated with survival in severe quetiapine overdose and may be an option in selected centers.⁶²

Treatment of Seizures

Seizures associated with antipsychotic overdose are generally short lived and often require no pharmacologic treatment. Multiple or refractory seizures should prompt a search for other causes, including hypoglycemia and ingestion of other proconvulsant medications. When treatment is necessary, benzodiazepines such as lorazepam or diazepam generally suffice, although phenobarbital may be necessary. Although phenytoin is part of the standard algorithm for status epilepticus, it is of limited effectiveness for xenobiotic-induced seizures; barbiturates such as phenobarbital or thiopental are preferred. Refractory seizures should respond to propofol infusion or general anesthesia. Seizures complicated by hyperthermia are considerably more ominous and warrant aggressive lowering of body temperature with aggressive rapid cooling measures. Finally, seizures can abruptly lower serum pH and may abruptly increase the cardiotoxicity of these drugs by enhancing binding to the sodium channel; therefore, an ECG should be obtained following resolution of seizure activity.

Treatment of the Central Antimuscarinic Syndrome

Many of the older and newer-generation antipsychotics have pronounced anticholinergic properties. Case reports and observational studies suggest that the cholinesterase inhibitor physostigmine (Antidotes in Depth: A9) can safely and effectively ameliorate the agitated delirium associated with the central anticholinergic syndrome by indirectly increasing synaptic acetylcholine concentrations.^{25,102–104} Doses of 1 to 2 mg are usual, administered cautiously after ensuring QRS widening is not present. Although benzodiazepines will control agitation, they will further impair alertness, obfuscating the assessment of mental status and increasing the risk of complications.²²

Physostigmine has been used successfully in patients with antipsychotic overdose,^{22,101,104,128,129} but it should be used with caution. It should not be used in patients with dysrhythmias, any degree of heart block, or widening of the QRS

complex. If physostigmine is used, it should be given in 0.5 mg increments slowly every 3 to 5 minutes, with close observation of the patient. If bradycardia, bronchospasm, or bronchorrhea develops, these can be treated with glycopyrrolate 0.2 to 0.4 mg IV. Atropine is often more widely available and could be used, but it crosses the blood–brain barrier and may aggravate any associated delirium. The effects of physostigmine are transient, typically ranging in duration from 30 to 90 minutes, and additional doses are often necessary. Of note, physostigmine does not prevent other complications of antipsychotic overdose, particularly those involving the cardiovascular system.

Other commonly used cholinesterase inhibitors, such as edrophonium, neostigmine, or pyridostigmine, should not be used to treat anticholinergic delirium because they do not cross the blood–brain barrier. Case reports involving other anticholinergics suggest that cholinesterase inhibitors used for treatment of dementia (eg, tacrine, donepezil, and galantamine) may be alternatives to physostigmine for patients able to take medications orally.^{51,74,85}

Enhanced Elimination

No pharmacologic rationale supports the use of multiple-dose activated charcoal or manipulation of urinary pH to increase the clearance of antipsychotics. One volunteer study found that urinary acidification may increase remoxipride elimination,¹³¹ but this practice is impractical and possibly dangerous. Because most antipsychotics exhibit large volumes of distribution and extensive protein binding (Table 70–1), extracorporeal removal is unwarranted and should be considered only if the patient has coingested other xenobiotics amenable to extracorporeal removal.

SUMMARY

- Over the past decade, atypical antipsychotics have supplanted traditional antipsychotic drugs, which were associated with greater toxicity in overdose and a higher incidence of extrapyramidal symptoms. Consequently, atypical antipsychotics are now implicated in the majority of overdoses.
- With all antipsychotics, significant toxicity can occur either during the course of therapy or following overdose.
- Of the various toxicities that arise during therapeutic use, NMS is the most dangerous. It may be difficult to recognize, but should be considered in any unwell patient treated with antipsychotics, particularly in the 2 weeks following a change in therapy or in a patient with severe intercurrent illness.
- The principal manifestations of antipsychotic overdose involve the CNS and cardiovascular system. Depressed mental status, hypotension, and anticholinergic signs are nonspecific features that support the diagnosis of antipsychotic overdose, particularly in conjunction with typical ECG findings of sodium channel blockade and QT interval prolongation. Most fatalities following antipsychotic overdose occur in cases involving coingestion of other CNS depressants or cardiotoxic medications.
- Supportive care is the mainstay of therapy for patients with antipsychotic overdose, although selective use of nonspecific antidotes, such as activated charcoal, sodium bicarbonate, or physostigmine may improve outcomes in selected patients. Particularly severe or refractory cardiovascular toxicity may warrant a trial of lidocaine or intravenous lipid emulsion, although these interventions are not well studied in this setting.

71 CYCLIC ANTIDEPRESSANTS

Erica L. Liebelt

HISTORY AND EPIDEMIOLOGY

The term cyclic antidepressant (CA) refers to a group of pharmacologically related xenobiotics used for treatment of depression, neuralgic pain, migraines, enuresis, and attention deficit hyperactivity disorder. Most CAs have at least three rings in their chemical structure. They include the traditional tricyclic antidepressants (TCAs) imipramine, desipramine, amitriptyline, nortriptyline, doxepin, trimipramine, protriptyline, and clomipramine, as well as other cyclic compounds such as maprotiline and amoxapine.

Imipramine was the first TCA used for treatment of depression in the late 1950s. However, the synthesis of iminodibenzyl, the “tricyclic” core of imipramine, and the description of its chemical characteristics date back to 1889. Structurally related to the phenothiazines, imipramine was originally developed as a hypnotic for agitated or psychotic patients and was serendipitously found to alleviate depression. From the 1960s until the late 1980s, the TCAs were the major pharmacologic treatment for depression in the United States. However, by the early 1960s, cardiovascular and central nervous system (CNS) toxicities were recognized as major complications of TCA overdoses. The newer CAs developed in the 1980s and 1990s were designed to decrease some of the adverse effects of older TCAs, improve the therapeutic index, and reduce the incidence of serious toxicity. Other CAs include the tetracyclic drug maprotiline and the dibenzoxapine drug amoxapine.

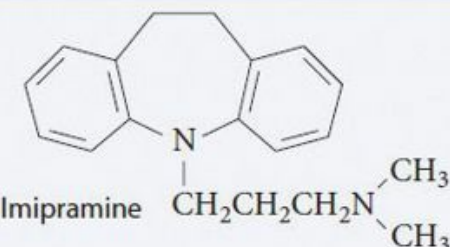

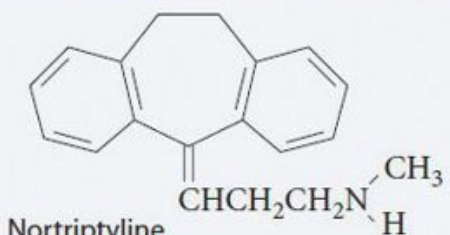

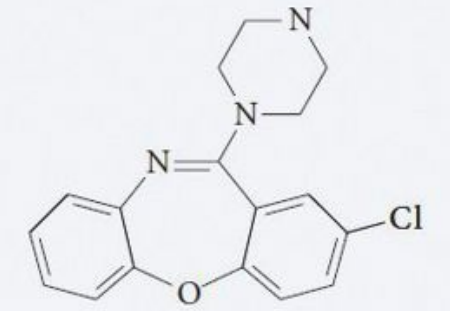

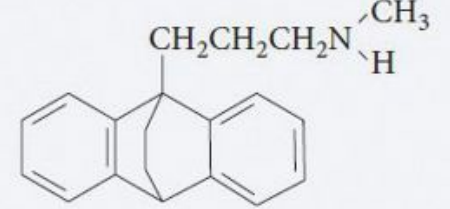

The epidemiology of CA poisoning has evolved significantly in the past 30 years, resulting in great part from the introduction of the selective serotonin reuptake inhibitors (SSRIs) and other newer antidepressants for the treatment of depression. Although the use of CAs for depression has decreased over the past 20 years, other medical indications, including chronic pain, obsessive-compulsive disorder, and, particularly in children, enuresis and attention deficit hyperactivity disorder have emerged, resulting in their continued use. The antidepressants are a leading cause of drug-related self-poisonings in the developed world, primarily because of their ready availability to people with depression or chronic pain who by virtue of their diseases are at high risk for overdose. However, despite the increase in SSRI use and overdose, patients with TCA overdoses continue to have higher rates of hospitalization and fatality than do those with SSRI overdose.

Children younger than 6 years have consistently accounted for approximately 12% to 13% of all CA exposures reported to poison centers during each of the last 15 years ([Chap. 136](#)). Despite the emergence of the SSRIs in the early 1990s, TCAs are still frequently prescribed by pediatric office based practices for many of the conditions noted above. Following the October 2004 US Food and Drug Administration Black Box Warning about the increased risk of suicidal behavior associated with antidepressant use, several reports have described significant declines in antidepressant dispensing in children compared to historical trends.²⁵ Nevertheless, CA poisoning likely will continue to be among the most lethal unintentional drug ingestions in younger children because only one or two adult-strength pills can produce serious clinical effects in young children.

PHARMACOLOGY

In general, the TCAs can be classified into tertiary and secondary amines based on the presence of a methyl group on the propylamine side chain ([Table 71–1](#)). The tertiary amines amitriptyline and imipramine are metabolized to the secondary amines nortriptyline and desipramine, respectively, which themselves are marketed as antidepressants. In therapeutic doses, the CAs produce similar pharmacologic effects on the autonomic system, CNS, and cardiovascular system. However, they can be distinguished from each other by their relative potencies.¹¹²

TABLE 71–1. Cyclic Antidepressants—Classification by Chemical Structure

Tertiary Amines	
Amitriptyline Clomipramine Doxepin Imipramine Trimipramine	 Imipramine
Secondary Amines	
Desipramine Nortriptyline Protriptyline	 Nortriptyline
Amoxapine	
Maprotiline	

At therapeutic doses, CAs inhibit presynaptic reuptake of norepinephrine and/or serotonin, thus functionally increasing the amount of these neurotransmitters at CNS receptors. The tertiary amines, especially clomipramine, are more potent inhibitors of serotonin reuptake, whereas the secondary amines are more potent inhibitors of norepinephrine reuptake. Although these pharmacologic actions formed the basis of the monoamine hypothesis of depression in the 1960s, antidepressant actions of these drugs appear to be much more complex.

Extensive research has led to the “receptor sensitivity hypothesis of antidepressant drug action,” which postulates that following chronic CA administration, alterations in the sensitivity of various receptors are responsible for antidepressant effects. Chronic TCA administration alters the number and/or function of central β -adrenergic and serotonin receptors. In addition, TCAs modulate glucocorticoid receptor gene expression and cause alterations at the genomic level of other receptors.⁸ All of these actions likely play a role in the antidepressant effects of TCAs.

Additional pharmacologic mechanisms of CAs are responsible for their side effects with therapeutic dosing and clinical effects following overdose. All of the CAs are competitive antagonists of the muscarinic acetylcholine receptors, although they have different affinities. The CAs also antagonize peripheral α_1 -adrenergic receptors. The most prominent effects of CA overdose result from binding to the cardiac sodium channels, which is also described as a membrane-stabilizing effect (Fig. 71–1) (Chap. 16). The tricyclic antidepressants are potent inhibitors of both peripheral and central postsynaptic histamine receptors. Finally, animal research demonstrates that the CAs interfere with chloride conductance by binding to the picrotoxin site on the γ -aminobutyric acid (GABA)–chloride complex.¹⁰²

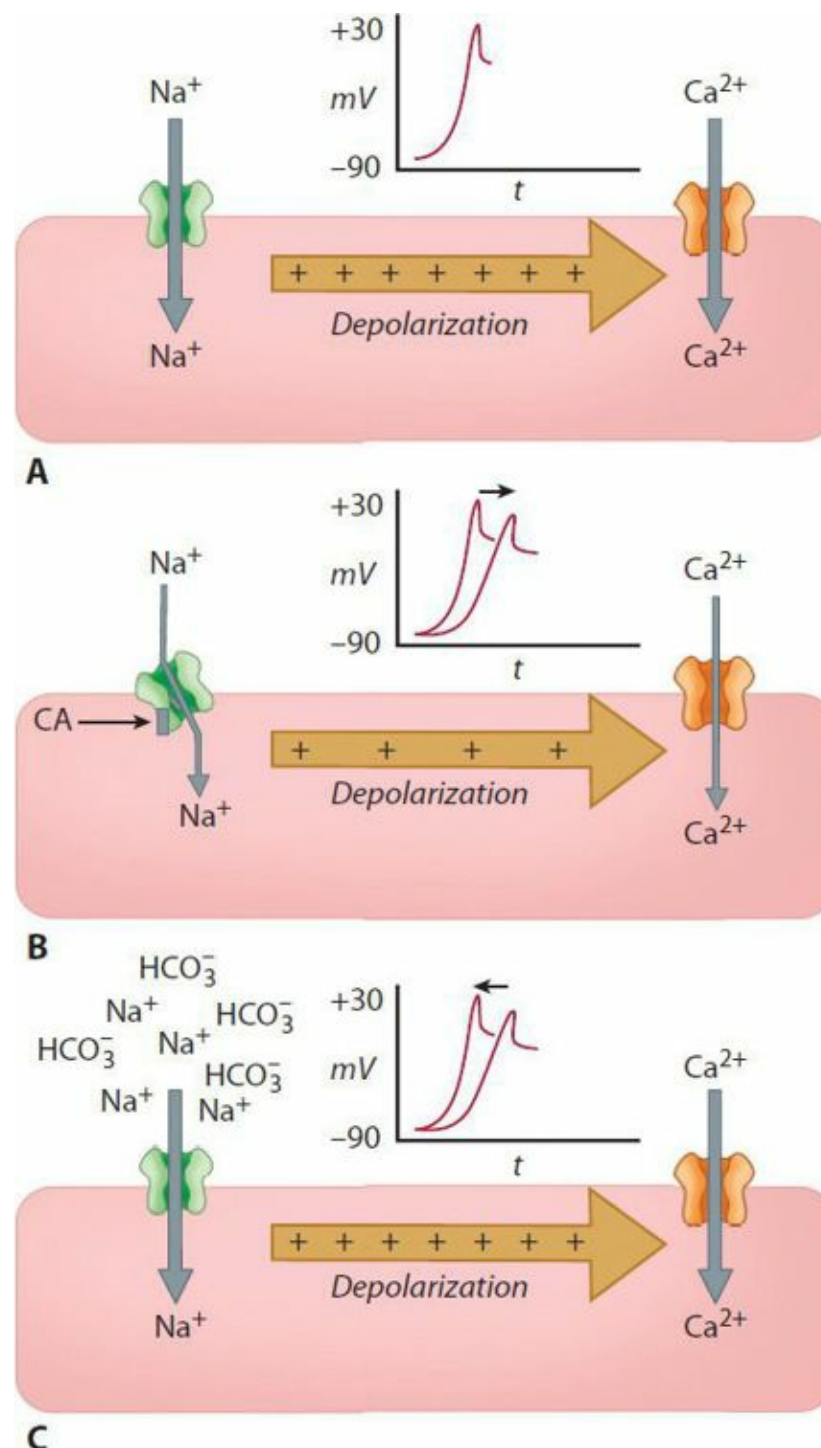

FIGURE 71-1. Effects of cyclic antidepressants (CAs) on the fast sodium channel. (A) Sodium depolarizes the cell, which both propagates conduction; allowing complete cardiac depolarization; and opens voltage-dependent Ca²⁺ channels, producing contraction. (B) CAs and other sodium channel blockers alter the conformation of the sodium channel, slowing the rate of rise of the action potential, which produces both negative dromotropic and inotropic effects. (C) Raising the Na⁺ gradient across the affected sodium channel speeds the rate of rise of the action potential, counteracting the drug-induced effects. Raising the pH removes the CA from the binding site on the Na⁺ channel. See Fig. 71-3 for the effects noted on the electrocardiograph.

Amoxapine is a dibenzoxapine CA derived from the active antipsychotic loxapine. Although it has a three-ringed structure, this drug has little similarity to the other tricyclics. It is a potent norepinephrine reuptake inhibitor, has no effect on serotonin reuptake, and blocks dopamine receptors. Maprotiline is a tetracyclic antidepressant that predominantly blocks norepinephrine reuptake. Both of these CAs have a slightly different toxic profile than the traditional TCAs.^{55,56,112}

PHARMACOKINETICS AND TOXICOKINETICS

The CAs are rapidly and almost completely absorbed from the gastrointestinal (GI) tract, with peak concentrations 2 to 8 hours after administration of a therapeutic dose. They are weak bases (high pK_a). In overdose, the decreased GI motility caused by anticholinergic effects and ionization in gastric acid delay CA absorption. Because of extensive first-pass metabolism by the liver, the oral bioavailability of CAs is low and variable, although metabolism may become saturated in

overdose, increasing bioavailability.

The CAs are highly lipophilic and possess large and variable volumes of distribution (15–40 L/kg). They are rapidly distributed to the heart, brain, liver, and kidney, where the tissue to plasma ratio generally exceeds 10:1. The octanol/water partition coefficient (Log P) is an often cited measure of lipid-solubility with the Log D representing Log P at physiological pH—a more representative measure. The latter pharmacologic property becomes important when evaluating the potential effectiveness of lipid emulsion therapy for CA toxicity. Some examples of Log D values for CAs are amitriptyline, 3.96; nortriptyline, 2.86; imipramine, 2.06; desipramine, 1.05; and doxepin, 2.93.

Less than 2% of the ingested dose is present in blood several hours after overdose, and serum CA concentrations decline biexponentially. The CAs are extensively bound to α_1 -acid glycoprotein (AAG) in the plasma, although differential binding among the specific CAs is observed.² Changes in AAG concentration or pH can alter binding and the percentage of free or unbound drug.^{87,95} Specifically, a low blood pH (which often occurs in a severely poisoned patient) may increase the amount of free drug, making it more available to exert its effects. This property serves as one basis for alkalization therapy (see below).

The CAs undergo demethylation, aromatic hydroxylation, and glucuronide conjugation of the hydroxy metabolites. The tertiary amines imipramine and amitriptyline are demethylated to desipramine and nortriptyline, respectively. The hydroxy metabolites of both tertiary and secondary amines are pharmacologically active and may contribute to toxicity. The glucuronide metabolites are inactive.

Genetically based differences in the activity of the CYP2D6 enzymes, which are responsible for hydroxylation of imipramine and desipramine, account for wide interindividual variability in metabolism and steady-state serum concentrations.¹⁹ “Poor metabolizers” may recover more slowly from an overdose or demonstrate toxicity with therapeutic dosing.¹⁰⁶ The metabolism of CAs also may be influenced by concomitant ingestion of ethanol and other medications that induce or inhibit the CYP2D6 isoenzyme (Chap. 13, Appendix). Patient variables such as age and ethnicity also affect CA metabolism.

Elimination half-lives for therapeutic doses of CAs vary from 7 to 58 hours (54–92 hours for protriptyline), with even longer half-lives in the elderly. The half-lives may also be prolonged following overdose as a result of saturable metabolism. A small fraction (15%–30%) of CA elimination occurs through biliary and gastric secretion. The metabolites are then reabsorbed in the systemic circulation, resulting in enterohepatic and enterogastric recirculation and reducing their fecal excretion. Finally, less than 5% of CAs are excreted unchanged by the kidney.

PATHOPHYSIOLOGY

The CAs slow the recovery from inactivation of the fast sodium channel, slowing phase 0 depolarization of the action potential in the distal His-Purkinje system and the ventricular myocardium (Fig. 71–1 and Fig. 22–2; Chap. 16). Impaired depolarization within the ventricular conduction system slows the propagation of ventricular depolarization, which manifests as prolongation of the QRS interval on the electrocardiogram (ECG) (Fig. 71–1). The right bundle branch has a relatively longer refractory period, and it is affected disproportionately by xenobiotics that slow intraventricular conduction. This slowing of depolarization results in a rightward shift of the terminal 40 millisecond (T40-msec) of the QRS axis and the right bundle branch block pattern that is noted on the ECG of patients who are exposed to, or overdose with, a CA.¹¹⁴

Because CAs are weakly basic, they are increasingly ionized as the ambient pH falls, and less ionized as the pH rises. Changing the ambient pH therefore likely alters their binding to the sodium channel. That is, since it is probable that 90% of the binding of CA to the sodium channel occurs in the ionized state, alkalinizing the blood facilitates the movement of the CA away from the hydrophilic sodium channel and into the lipid membrane.

Sinus tachycardia is due to the antimuscarinic, vasodilatory (reflex tachycardia), and sympathomimetic effects of the CAs. Wide-complex tachycardia most commonly represents aberrantly conducted sinus tachycardia rather than ventricular tachycardia. However, by prolonging anterograde conduction, nonuniform ventricular conduction may result, leading to reentrant ventricular dysrhythmias.

Electrophysiologic studies in a canine model demonstrate that QRS prolongation is rate dependent, a characteristic effect of the class I antidysrhythmics (Chap. 64). In these studies, when the heart rate could not accelerate because of a crushed sinus node, the dogs never developed QRS prolongation. Furthermore, pharmacologic induction of bradycardia prevents or narrows wide-complex tachycardia by allowing time for recovery of the sodium channel from inactivation.^{4,94} However, since bradycardia adversely affects cardiac output, induction of bradycardia is not recommended.

A Brugada ECG pattern, specifically type 1 or “coved” pattern, is rarely associated with CA overdose. The Brugada syndrome originates from a structural change in the myocardial sodium channel that results in functional sodium channel alterations similar to those caused by the CAs.^{11,77} It is possible that this small cohort of patients may have had subclinical Brugada syndrome that was uncovered by the CA (Chap. 16).

QT interval prolongation can occur in the setting of both therapeutic use and overdose of CAs. This apparent

prolongation of repolarization results primarily from slowed depolarization (ie, QRS prolongation) rather than altered repolarization.⁹⁰ Although QT prolongation predisposes to the development of torsade de pointes, this dysrhythmia is uncommon in patients with CA poisoning due to the prominent tachycardia.

Hypotension is caused by direct myocardial depression secondary to altered sodium channel function, which disrupts the subsequent excitation-contraction coupling of myocytes and impairs cardiac contractility. Peripheral vasodilation from α -adrenergic blockade by CAs also contributes prominently to postural hypotension. In addition, downregulation of adrenergic receptors may cause a blunted physiologic response to catecholamines.⁷⁶

Agitation, delirium, and depressed sensorium are primarily caused by the central anticholinergic and antihistaminic effects. Hemodynamic effects are likely to contribute in only the most severely poisoned patients. Details regarding the exact mechanism of CA-induced seizures remain elusive. CA-induced seizures may result from a combination of an increased concentration of monoamines (particularly norepinephrine), muscarinic antagonism, neuronal sodium channel alteration, and GABA inhibition.⁷⁸

Acute respiratory distress syndrome (ARDS) may occur in the setting of CA overdose. In one study, amitriptyline exposure caused dose-related vasoconstriction and bronchoconstriction in isolated rat lungs.¹⁰⁵ Many substances implicated in ARDS, such as platelet-activating factor and protein kinase activation, were important in mediating amitriptyline-induced impairment of lung function in this experimental model. Another animal model demonstrated that acute amitriptyline poisoning causes dose-dependent rises in pulmonary artery pressure, pulmonary edema, and sustained vasoconstriction that could be attenuated by either calcium channel inhibition or a nitric oxide donor.⁶⁶

CLINICAL MANIFESTATIONS

The toxic profile is qualitatively the same for all of the first-generation TCAs but is slightly different for some of the other CAs.¹¹² The progression of clinical toxicity is unpredictable and may be rapid. Patients commonly present to the emergency department (ED) with minimal apparent clinical abnormalities, only to develop life-threatening cardiovascular and CNS toxicity within hours.

The CAs have a low therapeutic index, meaning that a small increase in serum concentration over the therapeutic range may result in toxicity. Acute ingestion of 10 to 20 mg/kg of most CAs causes significant cardiovascular and CNS manifestations (therapeutic dose, 2–4 mg/kg/d). Thus, in adults, ingestions of more than 1 g of a CA is usually associated with life-threatening effects. As few as two 50 mg imipramine tablets may cause significant toxicity in a 10 kg toddler (ie, 10 mg/kg). In a series of children with unintentional TCA exposure, all patients with reported ingestions of more than 5 mg/kg manifested clinical toxicity.⁷²

Acute Toxicity

Most of the reported toxicity from CAs derives from patients with acute ingestions, especially in patients who are chronically taking the medication. Clinical manifestations of these two cohorts do not appear to be different, and most studies do not distinguish between them.

Acute Cardiovascular Toxicity. Cardiovascular toxicity is primarily responsible for the morbidity and mortality attributed to CAs. Refractory hypotension due to myocardial depression probably is the most common cause of death from CA overdose.^{20,104} Hypoxia, acidosis, volume depletion, seizures, or concomitant ingestion of other cardiodepressant or vasodilating drugs can exacerbate hypotension.

The most common dysrhythmia observed following CA overdose is sinus tachycardia (rate, 120–160 beats/min in an adult), and this finding is present in most patients with clinically significant TCA poisoning. The ECG typically demonstrates intraventricular conduction delay that manifests as a rightward shift of the T40-msec QRS axis and a prolongation of the QRS complex duration. These findings can be used to identify and risk stratify, respectively, patients with CA poisoning (see Diagnostic Testing). PR, QRS, and QT interval prolongation can occur in the setting of both therapeutic and toxic amounts of TCAs.⁶⁸

Wide-complex tachycardia is the characteristic potentially life-threatening dysrhythmia observed in patients with severe toxicity (**Fig. 71–2A–C**). Ventricular tachycardia may be difficult to distinguish from aberrantly conducted sinus tachycardia which occurs more commonly. In the former cases, the preceding P wave may not be apparent because of prolonged atrioventricular conduction, widened QRS interval, or both. Ventricular tachycardia occurs most often in patients with prolonged QRS complex duration and/or hypotension.^{63,108} Hypoxia, acidosis, hyperthermia, seizures, and β -adrenergic agonists may also predispose to ventricular tachycardia.^{63,108} Fatal dysrhythmias are rare, as ventricular tachycardia and fibrillation occur in only approximately 4% of all cases.^{41,85} Both the Brugada type I ECG pattern and torsade de pointes are uncommon with acute TCA overdose.

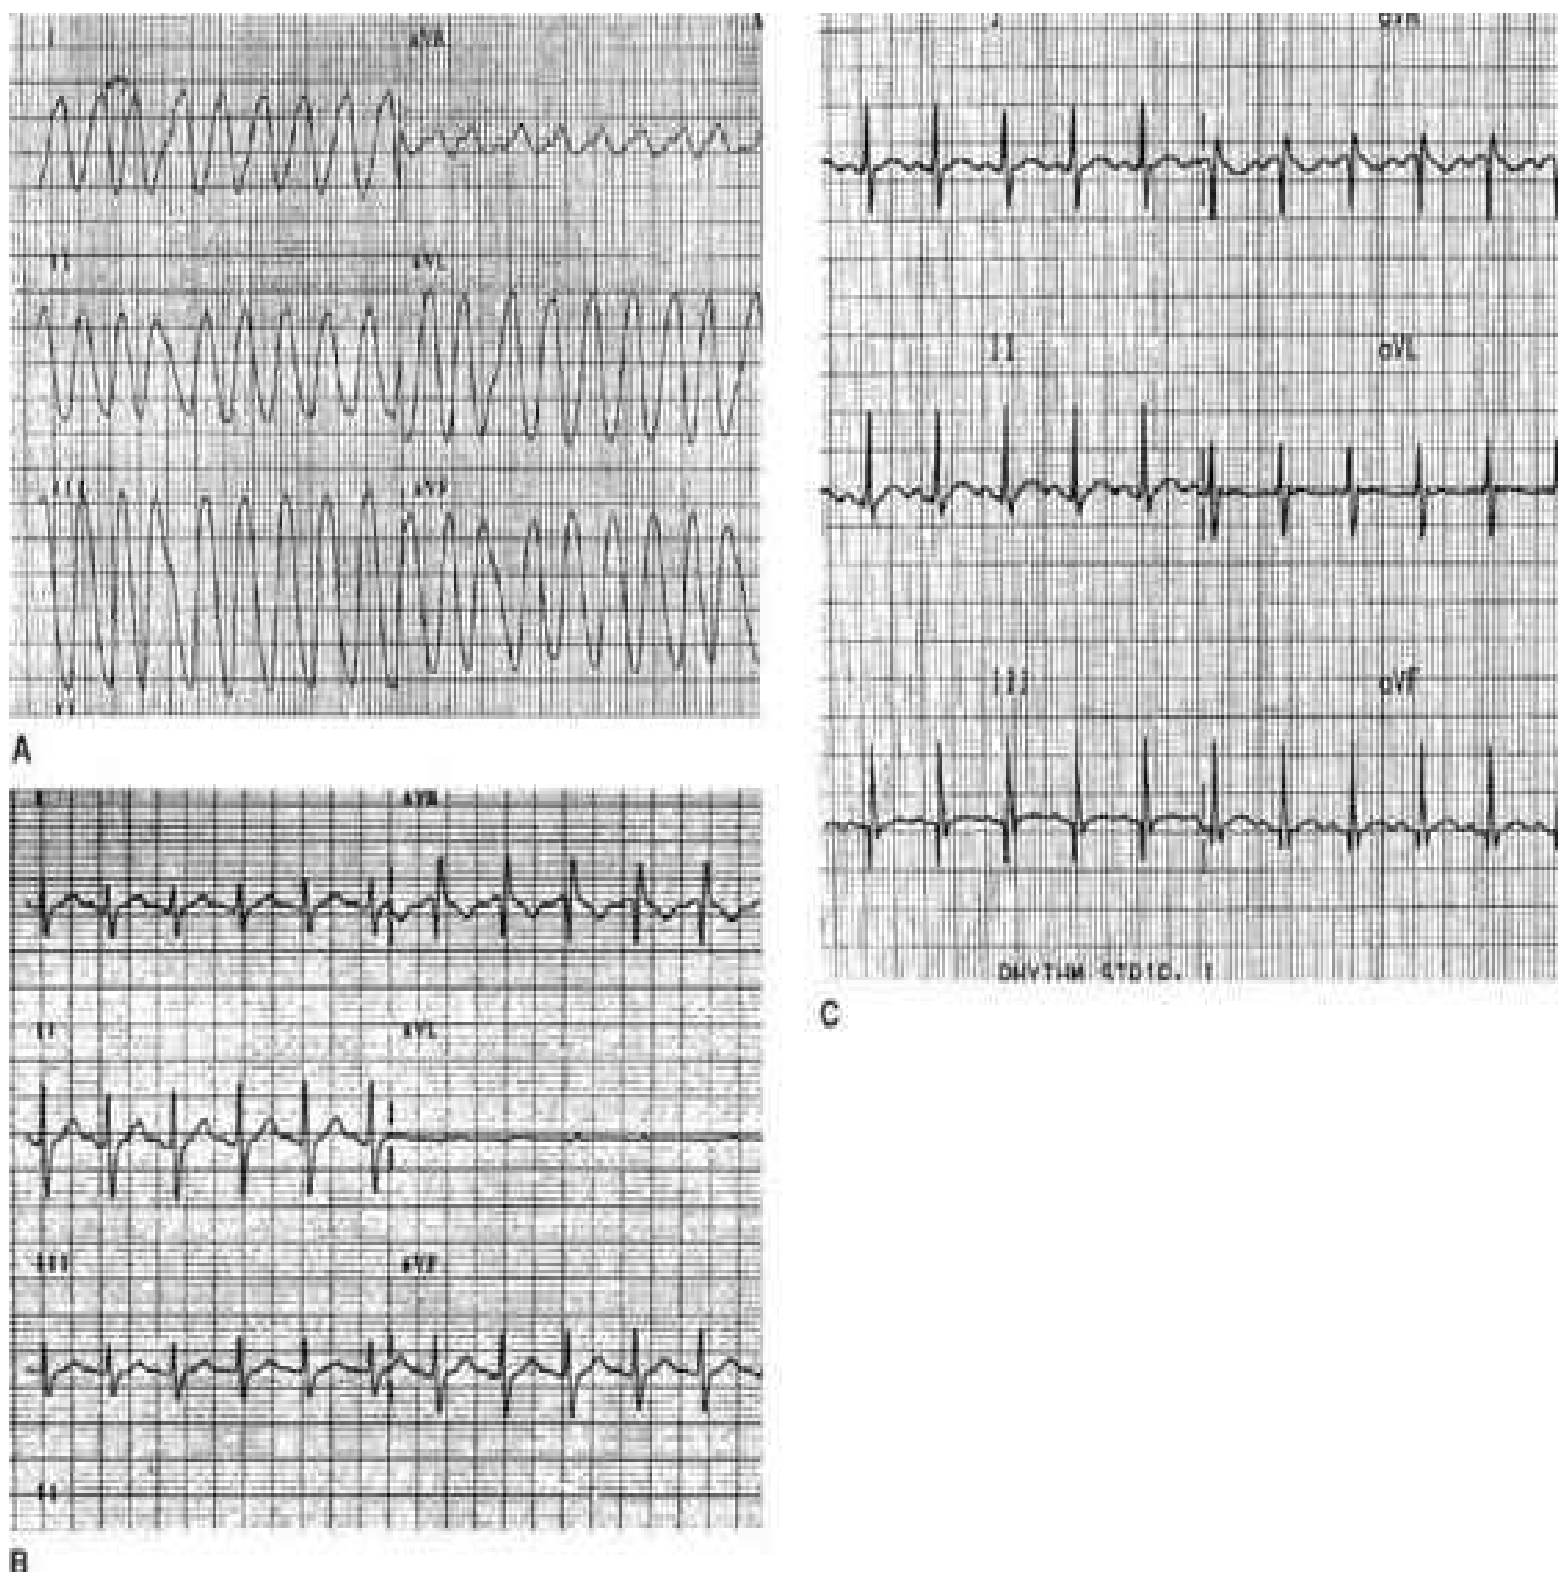

FIGURE 71-2. (A) Electrocardiograph (ECG) shows a wide-complex tachycardia with a variable QRS duration (minimum, 220 msec). (B) ECG 30 minutes after presentation following sodium bicarbonate shows narrowing of the QRS interval to a duration of 140 msec and an amplitude of RaV_R of 6.0 mm. (C) ECG 9 hours after presentation shows further narrowing of the QRS interval to 80 msec and decrease in the amplitude of RaV_R to 4.5 mm. (Reproduced with permission from Liebelt EL: Targeted management strategies for cardiovascular toxicity from tricyclic antidepressant overdose: the pivotal role for alkalization and sodium loading. *Pediatr Emerg Care*. 1998;14:293–298.)

Acute Central Nervous System Toxicity. Altered mental status and seizures are the primary manifestations of CNS toxicity. Delirium, agitation, and/or psychotic behavior with hallucinations may be present and most likely result from antagonism of muscarinic and histaminergic receptors. These alterations in consciousness usually are followed by lethargy, which is followed by rapid progression to coma. The duration of coma is variable and does not necessarily correlate or occur concomitantly with ECG abnormalities.⁵⁶

Seizures usually are generalized and brief, most often occurring within 1 to 2 hours of ingestion.²⁸ The incidence of seizures is similar to ventricular tachycardia and occurs in an estimated 4% of patients presenting with overdose and 13% of fatal cases.¹¹⁵ Status epilepticus is uncommon. Abrupt deterioration in hemodynamic status, namely hypotension and ventricular dysrhythmias, may develop during or within minutes after a seizure.^{28,63,108} This rapid cardiovascular

deterioration likely results from seizure-induced acidosis that exacerbates cardiovascular toxicity. The risk of seizures with CA overdoses may be increased in patients undergoing long-term therapy or who have other risk factors such as history of seizures, head trauma, or concomitant drug withdrawal.¹⁰⁰ Myoclonus and extrapyramidal symptoms may also occur in CA-poisoned patients.

Cessation of CAs may produce a drug discontinuation syndrome in some patients, which is typified by GI and somatic distress, sleep disturbances, movement disorders, and mania.³⁷

Other Clinical Effects. Anticholinergic effects can occur early or late in the course of CA toxicity. Pupils may be dilated and poorly reactive to light. Other anticholinergic effects include dry mouth, dry flushed skin, urinary retention, and ileus. Although prominent, these findings are typically clinically inconsequential.

Reported pulmonary complications include ARDS, aspiration pneumonitis, and multisystem organ failure. ARDS may be the result of aspiration, hypotension, pulmonary infection, and excessive fluid administration, along with the primary toxic effects of CAs.^{96,97} Bowel ischemia, pseudoobstruction, and pancreatitis are reported in patients with CA overdose.⁷⁴

Death directly caused by CA toxicity usually occurs in the first several hours after presentation and is secondary to refractory hypotension in patients who reach health care facilities. Late deaths (>1–2 days after presentation) usually are secondary to other factors such as aspiration pneumonitis, adult respiratory distress syndrome from refractory hypotension, and/or infection.²¹

Chronic Toxicity

Chronic CA toxicity usually manifests as exaggerated side effects, such as sedation and sinus tachycardia, or is identified by supratherapeutic drug concentrations in the blood in the absence of an acute overdose.³⁹ Unlike chronic theophylline and aspirin poisoning, chronic CA toxicity does not appear to cause life-threatening toxicity.

A sparse literature describes the clinical course of this cohort. However, a recent case report described chronic amitriptyline overdose in a child (15 mg/kg a day for a month), which resulted in status epilepticus and significant cardiac conduction abnormalities but normal neurological outcome.²⁶ Genetic analysis of this patient's CYP450 system showed two copies of wild-type alleles for the genes responsible for CYP2D6 activity; thus, concluding the patient was not a "rapid metabolizer." Several possible protective mechanisms are presented and further illustrate the complexity of this drug, its metabolism, and toxicity. These include a unique pharmacogenomics profile that yields an abnormal receptor profile or metabolic pathway (eg, polymorphism in the gene for myocardial fast sodium channels), another medication causing a beneficial drug-drug interaction, a cardioprotective role for caffeine if the patient's intake was high causing adenosine receptor antagonism and the protective effect from other drugs the patient was taking—guanfacine and clonidine—adrenergic medications that may have offered some protective effect from the α -adrenergic blockade caused by amitriptyline.

Several reports describe sudden death in children taking therapeutic doses of CAs.^{88,89,107} QT prolongation with resultant torsade de pointes, advanced atrioventricular conduction delays, blood pressure fluctuations, and ventricular tachycardia are postulated mechanisms, although whether any of these effects contributed to the deaths is unknown. Prospective studies using 12-lead ECG, 24-hour ECG recording, and Doppler echocardiography in children receiving therapeutic doses of CAs have failed to find any significant cardiac abnormalities when compared to children not taking CAs.^{14,31} However, authors recommend that CAs not be initiated or continued in any child with a resting QT interval greater than 450 msec or with bundle branch block.³⁴ This is an ongoing area of research as it becomes problematic in making decisions about pharmacotherapy interventions.

Unique Toxicity from “Atypical” Cyclic Antidepressants

Although the incidence of serious cardiovascular toxicity is lower in patients with amoxapine overdoses, the incidence of seizures is significantly greater than with the traditional CAs.^{56,65} Moreover, seizures may be more frequent, or status epilepticus may develop.⁷⁷ Similarly, the incidences of seizures, cardiac dysrhythmias, and duration of coma are greater with maprotiline toxicity compared to the CAs.⁵⁵

DIAGNOSTIC TESTING

Diagnostic testing for patients with CA poisoning primarily relies on indirect bedside tests (ECG) and other qualitative laboratory analyses. Quantification of CA concentration provides little help in the acute management of patients with CA overdose but provides adjunctive information to support the diagnosis.

Electrocardiography

The ECG can provide important diagnostic information and may predict clinical toxicity after a CA overdose. CA toxicity

results in distinctive and diagnostic ECG changes that may allow early diagnosis and targeted therapy when the clinical history and physical examination are unreliable.

A T40-msec axis between 120° and 270° is associated with CA toxicity and was a sensitive indicator of drug presence in one study.^{22,79,114} A terminal QRS vector between 130° and 270° discriminated between 11 patients with positive toxicology screens for CAs and 14 patients with negative toxicology screens.⁷⁹ With further analyses, this report concluded that the positive and negative predictive values of this ECG parameter for CA ingestions were 66% and 100%, respectively, in a population of 299 general overdose patients. A retrospective study reported that a CA-poisoned patient was 8.6 times more likely to have a T40-msec axis greater than 120° than was a non-CA-poisoned patient.¹¹⁴ This parameter was a more sensitive indicator of CA-induced altered mental status but not necessarily of seizure or dysrhythmia. However, the T40-msec axis is not easily measured in the absence of specialized computer-assisted analysis, which limits its practical utility. An abnormal terminal rightward axis can be estimated by observing a negative deflection (terminal S wave) in leads I and aV_L and a positive deflection (terminal R wave) in lead aV_R (Fig. 71-3).

FIGURE 71-3. (A) Normal QRS complex in lead aV_R . (B) Abnormal QRS complex in a patient with cyclic antidepressant (CA) poisoning. The R wave in lead aV_R is measured as the maximal height in millimeters of the terminal upward deflection in the QRS complex. In this example, the QRS complex duration is prolonged, indicating significant CA poisoning.

The maximal limb lead QRS complex duration is an easily measured ECG parameter that is a sensitive indicator of toxicity. One investigation reported that 33% of patients with a limb lead QRS interval greater than or equal to 100 msec developed seizures and 14% developed ventricular dysrhythmias.¹⁷ No seizures or dysrhythmias occurred in those patients whose QRS interval remained less than 100 msec. There was a 50% incidence of ventricular dysrhythmias among patients with a QRS duration greater than or equal to 160 msec. No ventricular dysrhythmias occurred in patients with a QRS duration less than 160 msec. Subsequent studies confirmed that a QRS duration greater than 100 msec is associated with an increased incidence of serious toxicity, including coma, need for intubation, hypotension, seizures, and dysrhythmias, making this ECG parameter a useful indicator of toxicity.^{22,61}

Evaluation of lead aV_R on a routine ECG may also predict toxicity (Figs. 71-2 and 71-3). When prospectively studied, 79 patients with acute CA overdoses demonstrated that the amplitude of the terminal R wave and R/S wave ratio in lead aV_R (R_{aV_R} , R/S_{aV_R}) were significantly greater in patients who developed seizures and ventricular dysrhythmias.⁶¹ The sensitivity of $R_{aV_R} = 3$ mm and $R/S_{aV_R} = 0.7$ in predicting seizures and dysrhythmias was comparable to the sensitivity of QRS = 100 msec.

The type 1 Brugada pattern is similar to a right bundle branch block (rSR'), with downsloping ST elevations ("coved") in the right precordial leads (V1–V3).^{11,77} This pattern is neither highly sensitive nor specific for CA toxicity, and it is reported in patients with cocaine and phenothiazine toxicity as well as those on class IA antidysrhythmic therapy. In one series of more than 400 patients with CA overdose, a significant increase in adverse outcomes (ie, seizures, widened QRS interval, and hypotension) was identified in those patients with a Brugada ECG pattern compared to those who did not have the pattern.¹¹ However, there were no deaths or dysrhythmias in the nine patients with this pattern.

Serial ECGs should be obtained because the ECG changes can be dynamic. ECG parameters should always be interpreted in conjunction with the clinical presentation, history, and course during the first several hours to assist in decision making regarding interventions and disposition.⁶²

Laboratory Tests

Determination of serum CA concentrations has limited utility in the immediate evaluation and management of patients with acute overdoses. In one study, serum drug concentrations failed to accurately predict the development of seizures or ventricular dysrhythmias.¹⁷ The pharmacologic properties of CAs—namely, large volumes of distributions, prolonged absorption phase, long distribution half-lives, pH-dependent protein binding, and the wide interpatient variability of terminal elimination half-lives—explain the limited value of serum concentrations in this situation. Any concentration above the therapeutic range (50–300 ng/mL, including active metabolites) may be associated with adverse effects, and is an indication to decrease or discontinue the medication.

Although CA concentrations greater than 1000 ng/mL usually are associated with significant clinical toxicity such as coma, seizures, and dysrhythmias, life-threatening toxicity may be observed in patients with serum concentrations less than 1000 ng/mL.^{17,57} Serious toxicity at lower concentrations probably results from a number of factors, including the timing of the specimen in relation to the ingestion and the limitations of measuring the concentration in blood and not the affected tissue. Quantitative concentrations usually cannot be readily obtained in most hospital laboratories. However, qualitative screens for CAs using an enzyme-multiplied immunoassay test are available at many hospitals. Unfortunately, false-positive results can occur with many drugs such as carbamazepine, cyclobenzaprine, thioridazine, diphenhydramine, quetiapine, and cyproheptadine (Chap. 6). Thus, the presence of a CA on a qualitative assay should not be relied upon to confirm the diagnosis of CA poisoning in the absence of corroborating historical or clinical evidence.

Quantitative concentrations may be helpful in determining the cause of death in suspected overdose patients. CA concentrations reported in lethal overdoses typically range from 1100–21,800 ng/mL. CA concentrations may increase more than fivefold because of postmortem redistribution (Chap. 34).⁵ Measurement of liver CA concentration or the parent-to-metabolite drug ratio may be useful in the postmortem setting.

MANAGEMENT

Any person with a suspected or known ingestion of a CA requires immediate evaluation and treatment (Table 71–2). The patient should be attached to a cardiac monitor, and intravenous access should be secured. Early intubation is advised for patients with CNS depression and/or hemodynamic instability because of the potential for rapid clinical deterioration. A 12-lead ECG should be obtained for all patients. Laboratory tests, including concentrations of glucose and electrolytes, should be performed for all patients with altered mental status, as well as blood gas analysis to both assess the degree of acidemia and guide alkalinization therapy. Aggressive interventions for maintenance of blood pressure and peripheral perfusion must be performed early to avoid irreversible damage. Both children and adults receiving cardiopulmonary resuscitation have recovered successfully despite periods of asystole exceeding 90 minutes.^{24,27,79,101} The options for GI decontamination discussed in the following section should then be considered.

TABLE 71–2. Treatment of Cyclic Antidepressant (CA) Toxicity

<i>Toxic Effect</i>	<i>Treatment</i>
Sinus rhythm with a QRS >100 msec	Sodium bicarbonate: 1–2 mEq/kg IV boluses at 3 to 5 minute intervals to reverse the abnormality or to a target serum pH ≤ 7.55 Controlled ventilation (if clinically indicated for hypoventilation)
Wide-complex tachycardia/ventricular tachycardia	Sodium bicarbonate: 1–2 mEq/kg IV boluses to reverse the dysrhythmias or to a target serum pH ≤ 7.55 Correct hypoxia, acidemia, hypotension Consider lidocaine: 1 mg/kg slow IV bolus, followed by infusion of 20–50 $\mu\text{g/kg/min}$ Consider hypertonic saline (3% sodium chloride) Consider magnesium sulfate 25–50 mg/kg (maximum 2 g) IV over 2 min Consider IV fat emulsion therapy 1.5 mL/kg bolus of 20%, repeated every 5 minutes until cardiovascular stability is restored; may consider infusion of 0.25 mL/kg per minute for 30 to 60 minutes with a maximum dose of 12 mL/kg
Torsade de pointes	Magnesium sulfate Overdrive pacing (caution due to rate dependence of CA)
Hypotension	0.9% sodium chloride boluses (up to 30 mL/kg) Correct hypoxia, acidemia Sodium bicarbonate: 1–2 mEq/kg IV boluses to a target serum pH of ≤ 7.55 Norepinephrine in standard titrated doses Consider IV fat emulsion therapy 1.5 mL/kg bolus of 20%, repeated every 5 minutes until cardiovascular stability is restored; may consider infusion of 0.25 mL/kg per minute for 30–60 minutes with a maximum dose of 12 mL/kg
Seizures	Benzodiazepines Secure airway with intubation if necessary Correct hypoxia, acidemia Barbiturates Continuous infusion of midazolam or propofol if barbiturates fail Consider neuromuscular paralysis/general anesthesia with EEG monitoring if all other measures fail
Refractory poisoning	Consider intravenous fat emulsion in moribund patients Consider extracorporeal mechanical circulation (extracorporeal membrane oxygenation, cardiopulmonary bypass), no evidence to support hemodialysis or hemoperfusion

Gastrointestinal Decontamination

Induction of emesis is contraindicated, given the potential for precipitous neurologic and hemodynamic deterioration. Because of the potential lethality of large quantities of CAs, orogastric lavage should be considered in the symptomatic patient with an overdose. Although the benefits of orogastric lavage for CA toxicity are not substantiated by controlled trials, the potential benefits of removing significant quantities of a highly toxic drug must be weighed against the risks of the procedure ([Chap. 8](#)).¹⁸ Because the anticholinergic actions of some CAs may decrease spontaneous gastric emptying, attempts at orogastric lavage up to 12 hours after ingestion may yield unabsorbed drug. Because of the potential for rapid

deterioration of mental status and seizures, orogastric lavage should be performed only after endotracheal intubation has ensured airway protection. Orogastric lavage in young children with unintentional ingestions of CAs may be associated with more risk and impracticalities, such as the inadequate hole size of pediatric tubes, and less benefit given the amount of drug usually ingested. Activated charcoal should be administered in nearly all cases. Irrespective of age, an additional dose of activated charcoal several hours later is reasonable in a seriously poisoned patient in whom unabsorbed drug may still be present in the GI tract or in the case of desorption of CAs from activated charcoal. It is important to monitor for the development of an ileus to prevent abdominal complications from additional doses of activated charcoal.⁷⁴

Wide-Complex Dysrhythmias, Conduction Delays, and Hypotension

The mainstay therapy for treating wide-complex dysrhythmias and for reversing conduction delays and hypotension is the combination of serum alkalinization and sodium loading. Increasing the extracellular concentration of sodium, or sodium loading, may overwhelm the effective blockade of sodium channels, presumably through gradient effects (Fig. 71-1). Controlled in vitro and in vivo studies in various animal models demonstrate that hypertonic sodium bicarbonate effectively reduces QRS complex prolongation, increases blood pressure, and reverses or suppresses ventricular dysrhythmias caused by CAs.^{82,92-94} These studies showed a clear benefit of hypertonic sodium bicarbonate when compared to hyperventilation, hypertonic sodium chloride, or nonsodium buffer solutions. A systematic review of all animal and human studies published before 2001 revealed that alkalinization therapy was the most beneficial therapy for consequential dysrhythmias and shock¹⁶ (Antidotes in Depth: A5).

The optimal dosing and mode of administration of hypertonic sodium bicarbonate and the indications for initiating and terminating this treatment are unsupported by controlled clinical studies. Instead, the information is extrapolated from animal studies, clinical experience, and an understanding of the pathophysiologic mechanisms of CA toxicity. A bolus, or rapid infusion over several minutes, of hypertonic sodium bicarbonate (1–2 mEq/kg) should be administered initially.^{70,98} Additional boluses every 3 to 5 minutes can be administered until the QRS interval narrows and the hypotension improves (Fig. 71-2). Blood pH should be carefully monitored after several bicarbonate boluses, aiming for a target pH of no greater than 7.50 or 7.55. Because CAs may redistribute from the tissues into the blood over several hours, it may be reasonable to begin a continuous sodium bicarbonate infusion to maintain the pH in this range. Differences in outcomes between repetitive boluses versus bicarbonate infusions are not well studied. Although diluting sodium bicarbonate in 5% dextrose in water and infusing it slowly renders it less able to increase the sodium gradient across the cell, the beneficial effects of pH elevation still warrant its use once the patient is stabilized. No evidence supports prophylactic alkalinization in the absence of cardiovascular toxicity (eg, QRS < 100 msec). In addition, alkalization would inevitably cause a decrease in potassium, which may cause QT prolongation and potentially contribute to other dysrhythmias. Hypertonic sodium chloride (3% NaCl) reverses cardiotoxicity in several animal studies,^{47,71,82} and numerous reports and extensive clinical experience support its efficacy in humans.^{16,48,49,73} However, the dose of hypertonic saline for CA poisoning has never been evaluated in humans for safety or efficacy, and the dose suggested by animal studies (up to 15 mEq/kg) exceeds the amount that most clinicians would consider safe (1–2 mEq/kg). Hypertonic sodium chloride is associated with a hyperchloremic metabolic acidosis, an undesired effect that highlights one benefit of hypertonic sodium bicarbonate. However, hypertonic saline could be considered in situations in which alkalinization with sodium bicarbonate is not possible.

Hyperventilation of an intubated patient is a more rapid and easily titratable method of serum alkalinization but is not as effective as sodium bicarbonate in reversing cardiotoxicity.^{51,70} Simultaneous hyperventilation and sodium bicarbonate administration may result in profound alkalemia and should be performed only with extreme caution and careful monitoring of pH. Hyperventilation without bicarbonate administration may be indicated in patients with ARDS or congestive heart failure in whom administration of large quantities of sodium is contraindicated.

Alkalinization and sodium loading with hypertonic sodium bicarbonate and or hypertonic saline along with controlled ventilation (if clinically indicated) should be administered to all CA overdose patients presenting with major cardiovascular toxicity and altered mental status. Indications include conduction delays (QRS > 100 msec) and hypotension. It is imperative to initiate treatment until CA toxicity can be excluded because of the risk of rapid and precipitous deterioration. Although commonly assumed, it is unclear whether the failure of the QRS complex to narrow with sodium bicarbonate treatment excludes CA toxicity.

It is unclear whether alkalinization and sodium loading is effective for reversing the Brugada pattern. The sparse available literature is equivocal.^{12,77} It would seem prudent to administer sodium bicarbonate in the presence of a presumed CA-induced Brugada pattern, especially with concomitant signs of other CA toxicity.

Alkalinization may be continued for at least 12 to 24 hours after the ECG has normalized because of the redistribution of the drug from the tissue. However, the time observed for resolution or normalization of conduction abnormalities is extremely variable, ranging from several hours to several days, despite continuous bicarbonate infusion.⁶² We recommend stopping alkalinization when the patient's mental status improves and there is improvement, but not necessarily normalization, of abnormal ECG findings.

Antidysrhythmic Therapy

Lidocaine is the antidysrhythmic most commonly advocated for treatment of CA-induced dysrhythmias, although no controlled human studies demonstrate its efficacy.⁸⁶ Because lidocaine has sodium channel blocking properties, some investigators argue against its use in CA poisoning.¹ These theoretical concerns are not well supported in the literature, and the class IB antidysrhythmic channel binding kinetics may prove favorable. Although limited data also suggest that the IB antidysrhythmic phenytoin prevents or reverses conduction abnormalities,^{43,69} these data were poorly controlled for other confounding factors, such as blood pH and sodium bicarbonate administration; they had very small numbers; and, in some, the cardiotoxicity was not severe. Since phenytoin exacerbates ventricular dysrhythmias in animals²¹ and fails to protect against seizures,¹⁰ its use is no longer recommended.

The use of class IA (quinidine, procainamide, disopyramide, and moricizine) and class IC (flecainide, propafenone) antidysrhythmics is absolutely contraindicated because they have similar pharmacologic actions to CAs and thus may worsen the sodium channel inhibition and exacerbate cardiotoxicity. Class III antidysrhythmics (amiodarone, bretylium, and sotalol) prolong the QT interval and, although unstudied, may be contraindicated as well (Chap. 64).

Because magnesium sulfate has antidysrhythmic properties, it may be beneficial in the treatment of ventricular dysrhythmias. Animal studies of the effects of magnesium on CA-induced dysrhythmias yield conflicting results.^{52,53} However, successful use of magnesium sulfate in the treatment of refractory ventricular fibrillation after TCA overdose is reported.^{24,27,54,91} A case control study suggested that magnesium sulfate and sodium bicarbonate resulted in lower fatality incidence and shorter intensive care unit stay compared to sodium bicarbonate alone.²⁹ When dysrhythmias fail to reverse after alkalization, sodium loading, and a trial of lidocaine, or magnesium sulfate may be warranted.

Slowing the heart rate in the presence of CAs may allow more time during diastole for CA unbinding from sodium channels and result in an improvement in ventricular conduction.^{3,92} This may abolish the reentry mechanism for dysrhythmias and was one rationale for the past use of physostigmine and propranolol. Thus, decreasing the sinus rate may itself be effective in abolishing ventricular dysrhythmias by eliminating rate-dependent conduction slowing. Propranolol terminated ventricular tachycardia in an animal model but also caused significant hypotension and death.⁹⁴ In one case series, patients developed severe hypotension or had a cardiac arrest shortly after receiving a β -adrenergic antagonist.³⁶ Other animal studies suggest that preventing or abolishing tachycardia by sinus node destruction, or by using bradycardic agents that impede sinus node automaticity without affecting myocardial repolarization or contractility, may successfully prevent CA-induced ventricular dysrhythmias.^{3,4} The combined negative inotropic effects of β -adrenergic antagonists and CAs, along with the significant cardiac and CNS effects reported with physostigmine use, do not support their routine use in the management of CA-induced tachydysrhythmias.

Hypotension

Standard initial treatment for hypotension should include volume expansion with isotonic saline or sodium bicarbonate. Hypotension unresponsive to these therapeutic interventions necessitates the use of inotropic or vasopressor support and possibly extracorporeal cardiovascular support.

No controlled human trials are available to guide the use of vasopressor therapy. The pharmacologic properties of CAs complicate the choice of a specific agent. Specifically, CA blockade of neurotransmitter reuptake theoretically could result in depletion of intracellular catecholamines. This could blunt the effect of dopamine, which is dependent on the release of endogenous norepinephrine for its inotropic activity. This suggests that a direct-acting vasopressor such as norepinephrine is more efficacious than an indirect-acting catecholamine such as dopamine.

In fact, limited clinical data suggest that norepinephrine is more efficacious than dopamine.¹⁰⁹ In a retrospective study of 26 adult hypotensive patients receiving nonstandardized therapy, response rates to norepinephrine (5–53 $\mu\text{g}/\text{min}$) were significantly better than response rates to dopamine (5–10 $\mu\text{g}/\text{kg}/\text{min}$).¹¹⁰ Patients who did not respond to dopamine at vasopressor doses (10–50 $\mu\text{g}/\text{kg}/\text{min}$) responded to norepinephrine (5–74 $\mu\text{g}/\text{min}$). Animal data comparing various treatments are conflicting, and their direct applicability to clinical human poisoning is limited.^{32,111} Both norepinephrine and epinephrine increased the survival rate in CA-poisoned rats. In addition, epinephrine was superior to norepinephrine when used both with and without sodium bicarbonate, and the most effective treatment regimen in this study was epinephrine plus sodium bicarbonate; neither precipitated dysrhythmias. The authors propose that epinephrine is more efficacious because it augments myocardial perfusion more than norepinephrine and improves the recovery of CA sodium channel blockade by hyperpolarization of the membrane potential through its stimulation of increased potassium intracellular transport.

Based on the available data, pharmacologic effects, theoretical concerns, and experience, norepinephrine (0.1–0.2 $\mu\text{g}/\text{kg}/\text{min}$) is recommended for hypotension that is unresponsive to volume expansion and hypertonic sodium bicarbonate therapy. Central venous pressure and or pulmonary artery catheterization may be necessary to guide the choice of additional vasopressor or inotropic agents, especially in the presence of other cardiodepressant drugs.

If these measures fail to correct hypotension, extracorporeal life support measures should be considered.

Extracorporeal membrane oxygenation, extracorporeal circulation, and cardiopulmonary bypass are successful adjuncts for refractory hypotension and life support when maximum therapeutic interventions fail.^{42,101,113} These modalities can provide critical perfusion to the heart and brain and maintain metabolic function while giving the body time to metabolize and eliminate the CA by maintaining hepatorenal blood flow.

Emerging Therapies

Vasopressin is increasingly being used in the setting of vasodilatory shock with successful increases in arterial blood pressure based on its vasoconstrictive actions from several mechanisms. Its successful use for intractable hypotension due to CA toxicity, unresponsive to α -receptor agonists and pH manipulation, has been described and warrants further investigation.⁹

Intravenous fat emulsion is reported to be effective in reversing cardiovascular toxicity due to several lipophilic drugs including amitriptyline and clomipramine. Its utilization and effectiveness appears logical given their pharmacological properties—Log D and Log P—octanol/water partition coefficient discussed previously.

Several controlled animal studies have demonstrated improved survival in clomipramine-induced cardiovascular collapse when intravenous lipid emulsion is given either as pretreatment or resuscitation in comparison with saline controls and sodium bicarbonate infusion.⁴⁴ Other animal studies failed to demonstrate any benefit.^{7,64} Specifically, one failed to demonstrate a statistically significant benefit in amitriptyline-poisoned rats pretreated with intravenous fat emulsion.⁷ Case series and case reports demonstrate clinical improvement when lipids have been administered for cardiovascular collapse or instability refractory to other therapies.^{38,44,50,58,99} The dosing and timing of administration are variable as well as other concomitant therapies, making it difficult to reach any definitive conclusions regarding its effectiveness. In addition, significant adverse reactions and complications have been noted including ARDS and pancreatitis. More data is emerging allowing more evidence-based criteria for its use and dosing. Certainly for patients with refractory hypotension and or ventricular dysrhythmias, fat emulsion therapy should be strongly considered, given the high mortality rate with these medications (Antidotes in Depth: A20).

Central Nervous System Toxicity

Seizures caused by CAs usually are brief and may stop before treatment can be initiated. Recurrent seizures, prolonged seizures (>2 minutes), and status epilepticus require prompt treatment to prevent worsening acidosis, hypoxia, and development of hyperthermia and rhabdomyolysis. Benzodiazepines are effective as first-line therapy for seizures. If this therapy fails, barbiturates or propofol should be administered. Propofol controlled refractory seizures resulting from amoxapine toxicity.⁷⁵ Failure to respond to barbiturates or propofol should lead to consideration of neuromuscular paralysis and general anesthesia with continuous electroencephalographic monitoring. Phenytoin is not recommended for seizures because data not only demonstrate a failure to terminate seizures but also suggest enhanced cardiovascular toxicity.^{9,21}

Use of flumazenil in a patient with known or suspected CA ingestion is contraindicated. Several case reports of patients with CA overdoses describe seizures following administration of flumazenil⁵⁹ (Antidotes in Depth: A27). Physostigmine was used in the past to reverse the acute CNS toxicity of CAs (Antidotes in Depth: A9). However, physostigmine is not recommended because it may increase the risk of cardiac toxicity, cause bradycardia and asystole, and precipitate seizures in acutely CA-poisoned patients.⁸⁴

Enhanced Elimination

No specific treatment modalities have demonstrated clinical significant efficacy in enhancing the elimination of CAs. Some investigators propose multiple doses of activated charcoal to enhance CA elimination because of their small enterohepatic and enterogastric circulation.⁶⁷ Human volunteer studies and case series of patients with CA overdoses suggest that the half-life of CAs may be decreased by multiple-dose activated charcoal (MDAC).¹⁰⁷ Activated charcoal reduced the apparent half-life of amitriptyline to 4 to 40 hours in overdose patients, compared to previously published values of 30 to more than 60 hours.¹⁰⁷ Changes in the severity or duration of clinical toxicity, however, were not reported. Other investigators showed that in human volunteers MDAC reduced the half-life of therapeutic doses of amitriptyline approximately 20% compared with no activated charcoal administration. However, the methodologic flaws and equivocal findings of these studies and the lack of any positive outcome data for this intervention from additional studies do not provide evidence supporting its use in this setting.^{23,40} Pharmacokinetic properties of CAs (large volumes of distribution, high plasma protein binding) weighed against the small increases in clearance and the potential complications of MDAC, such as impaction, intestinal infarction, and perforation, do not warrant its routine use.^{23,74} One additional dose of activated charcoal may be given to decrease GI absorption in patients with evidence of significant CNS and cardiovascular toxicity if bowel sounds are present.

Measures to enhance urinary CA excretion have a minimal effect on total clearance. Urinary alkalization does not

enhance, and may reduce, urinary clearance due to passive reabsorption of the unionized CA from an alkaline urine. Hemodialysis is ineffective in enhancing the elimination of CAs because of their large volumes of distribution, high lipid solubility, and extensive protein binding.⁴⁵ Hemoperfusion overcomes some of the limitations of hemodialysis but may not be effective because of the large volumes of distributions of CAs. Although several uncontrolled case reports and a case series described improvement in cardiotoxicity during hemoperfusion, this finding may be coincidental.^{13,24,35}

Hospital Admission Criteria

All patients who present with known or suspected CA ingestion should undergo continuous cardiac monitoring and serial ECG for a minimum of 6 hours. Recommendations in the older literature for 48 to 72 hours of intensive care unit monitoring even for patients with minor CA ingestions stem from isolated case reports of late-onset dysrhythmias, CNS effects, and sudden deaths.⁸³ However, review of these cases shows inadequate GI decontamination, inadequate therapeutic interventions, and significant ongoing complications of overdose. Several retrospective studies demonstrate that late, unexpected complications in CA overdoses such as seizures, dysrhythmias, and death did not occur in patients who had few or no major signs of toxicity at presentation or a normal level of consciousness and a normal ECG for 24 hours.^{20,27,30,85} A disposition algorithm has been proposed based on clinical signs and symptoms.^{6,108} If the patient is asymptomatic at presentation, undergoes GI decontamination, has normal ECGs, or has sinus tachycardia (with normal QRS complexes) that resolves, and the patient remains asymptomatic in the health care facility for a minimum of 6 hours without any treatment interventions, the patient may be medically cleared for psychiatric evaluation (if appropriate) or discharged home as appropriate.

A prospective study of 67 patients used the Antidepressant Overdose Risk Assessment (ADORA) criteria to identify patients who were at high risk for developing serious toxicity and proposed criteria for hospitalization.³³ In this study, the presence of QRS interval greater than 100 msec, cardiac dysrhythmias, altered mental status, seizures, respiratory depression, or hypotension on presentation to the ED (or within 6 hours of ingestion, if the time was known) was 100% sensitive in identifying patients with significant toxicity and subsequent complications. Criteria specific for intensive care unit admission (other than patients requiring ventilatory and or blood pressure support), versus an inpatient bed with continuous cardiac monitoring, are less clear and probably are institution dependent.¹⁰³

The disposition of patients with persistent isolated sinus tachycardia, prolonged QT interval with no concomitant altered mental status, or blood pressure changes, is not clearly defined. Previous studies demonstrate that these two parameters alone are not predictive of subsequent clinical toxicity or complications.^{33,34} In addition, the sinus tachycardia may persist for up to one week following ingestion. However, a study of isolated CA overdose patients reported that a heart rate greater than 120 beats/min and QT interval greater than 480 msec were associated with an increased likelihood of major toxicity.²² These patients are candidates for observation units with continuous ECG monitoring and serial ECGs for 24 hours.

Inpatient Cardiac Monitoring

The duration of cardiac monitoring in any patient initially exhibiting signs of major clinical toxicity depends on many factors. Certainly the duration of CA cardiotoxicity and neurotoxicity may be prolonged, and using normalization of ECG abnormalities as an end point for therapy and discharge is problematic. Some studies document the variable resolution and normalization of QRS prolongation and T40-msec axis rotation.^{81,97} Based on the available literature, it is reasonable to recommend that after the mental status and blood pressure normalize, and the ECG improves, patients who exhibited significant poisoning should be monitored for another 24 hours off of all of therapy, including alkalization, antidysrhythmics, and inotropics/vasopressors.

SUMMARY

- CA poisoning continues to be a cause of serious morbidity and mortality worldwide.
- The distinctive characteristics of these drugs can cause significant CNS and cardiovascular toxicity, the latter being responsible for mortality as a result of overdose of these drugs. Cardiovascular toxicity ranges from mild conduction abnormalities and sinus tachycardia to wide-complex tachycardia, hypotension, and asystole. CNS toxicity includes delirium, lethargy, seizures, and coma.
- The ECG is a simple, readily available diagnostic test that can predict the development of significant toxicity, particularly seizures and/or dysrhythmias.
- Management strategies are based primarily on the pathophysiology of these drugs, namely, sodium channel blockade in the myocardium. Alkalization and sodium loading with hypertonic sodium bicarbonate is the principal therapy for cardiovascular toxicity.
- Guidelines for observing or admitting patients to the hospital may be based on initial clinical presentation or

development of clinical effects and ECG changes.

72 LITHIUM

Howard A. Geller

Lithium	
MW	= 6.94 Da
Lithium concentration (serum):	
Therapeutic concentration for bipolar depression	= 0.6–1.2 mEq/L (mmol/L)

HISTORY AND EPIDEMIOLOGY

The Swedish chemistry student Arfwedson discovered lithium in 1817.^{8,131} Lithium derives its name from the Greek word for stone, lithos, from which it was first isolated. The therapeutic use of lithium has a long history beginning in the mid 19th century, when lithium salts were used to treat individuals with gout and were noted to improve symptoms of mania and depression.¹¹⁶ The soft drink 7-Up was originally formulated with lithium as its “active ingredient.”⁸ During the 1930s and 1940s, lithium was used as a salt substitute (“Westsal”) for patients with congestive heart failure but was discontinued after several cases of acute lithium poisoning were described.⁸⁷ The beneficial effects of lithium on bipolar disorder were “rediscovered” by Cade in 1949, when he noticed the calming effect of lithium carbonate on guinea pigs.⁵² The same year, however, the US Food and Drug Administration (FDA) banned the use of lithium in response to reported poisonings.¹³⁹ The FDA lifted the ban in 1970 and approved the use of lithium for the treatment of mania.

Currently, lithium is the most efficient long-term therapy for treatment and prevention of bipolar affective disorders,^{51,81} with a demonstrated antisuicidal effect and an ability to improve the manic and depressive symptoms of the illness, as well as to augment the therapeutic efficacy of other therapies that have failed to achieve symptom remission.^{16,45,53,78,81,108,111,131} Investigations on the use of lithium for compulsive gambling have also demonstrated beneficial results,⁹³ and it is under investigation for use in neurodegenerative disorders such as Alzheimer disease, stroke, amyotrophic lateral sclerosis, Huntington disease, multiple sclerosis, and traumatic brain injury.^{23,47,142,199} In most industrialized nations, approximately one in 1000 persons is prescribed one or more of the various lithium formulations.^{84,121,122}

PHARMACOLOGY

Lithium, the simplest xenobiotic in the modern pharmacopoeia, has a complex mechanism of action that has not been completely elucidated even after more than 50 years of clinical use. Psychotropics modifying monoamine neurotransmission form the basis of modern psychopharmacology. The current paradigm of neuropsychiatric therapeutics implies that because xenobiotics that affect the neurotransmission of dopamine are most efficacious, this receptor-drug exemplar defines the disease. Multiple lines of investigation have shown that beyond simple monoamine balance, the interaction between multiple signaling cascades, neurotrophic and neuroprotective systems is not only involved in the pathogenesis of mood disorders, but also the cellular and molecular means of the action of lithium.¹⁵⁵ Additionally, the understanding that a particular receptor only undergoes a single agonist-receptor activation has been replaced by the growing comprehension that agonist binding causes activation of multiple pathways of downstream signaling, with a myriad of results.²⁵ Lithium illustrates this new paradigm through its multiple direct and indirect effects.

Clinically, the therapeutic effects of lithium and similar mood-stabilizing pharmaceuticals become evident only after chronic administration, so their mechanism of action is unlikely solely the result of acute biochemical interactions. One of the central processes involved in the therapeutic effects of lithium, and potentially the pathogenesis of mood disorders, is its interaction with the β form of glycogen synthase kinase 3 (GSK-3). GSK-3 β is a serine/threonine kinase originally described with the regulation of glycogen synthesis in response to insulin.²⁵ Subsequently it has been shown to influence multiple systems, including gene transcription, neuronal function and neurogenesis, synaptic plasticity, and the circadian cycle, as well as cellular structure, apoptosis, and cell death. In fact, GSK-3 β phosphorylates more than 100 substrates, with a suggestion of many more.¹⁰¹ Each of these systems are implicated in the pathophysiology of mood disorders.^{25,155}

Postmortem tissue from the ventral prefrontal cortex of patients with major depressive disorder showed elevated GSK-3 β activity as well as decreased activity in the GSK-3 β modifying enzyme, Akt (also known as protein kinase B).^{102,103} GSK-3 β is inadequately inhibited in association with mood disorders and is inhibited in humans treated with lithium.¹⁰¹ Overactivity of this enzyme is associated with neuronal degeneration and sensitivity to apoptotic stimulation. Dysregulation of GSK-3 β is implicated in tumor growth and the neurofibrillary tangles of Alzheimer disease.^{56,191} It also is a key regulator of neuronal cell fate, with a proapoptotic effect in many settings.^{5,22,24,26,101,118,131,161} It is involved in regulating the activity of β -catenin, Jun, and cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB), transcription factors important in embryonic patterning, cell proliferation, neuronal modeling and plasticity, neuronal signal transduction, memory consolidation, and cytoskeletal remodeling. Its other targets include transcription factors such as c-Jun, nuclear factor activated T-cells, proteins bound to microtubules (Tau, microtubule-associated protein 1B, kinesin light chain), cell cycle mediators (cyclin D), and metabolic regulators (glycogen synthase, pyruvate dehydrogenase).^{153,155} Hypoxia contributes to increased GSK-3 β activity, which may be counteracted or inhibited with mood-stabilizing drugs. Vascular depression, or depression after stroke, is an organic model of major depression.^{94,133} The finding that this depressive state responds similarly to intervention with mood stabilizers lends further support to the GSK-3 β hypothesis.^{70,79,90,150,190}

Many older generation antipsychotics are now known to affect GSK-3 β signaling in mice.¹¹⁹ GSK-3 β activity is regulated not only by first- and second-generation antipsychotics but also through 5-HT neurotransmission and activation of 5-HT_{2A} receptors as well as through monoamine-affecting antidepressants which modify these neurotransmitters.^{22–28,117} Atypical antipsychotics and antagonists of D₂ dopamine receptors, as well as 5-HT_{2A} serotonin receptors, may exert some of their utility through inhibition of GSK-3 β activity.^{22,25}

The link between neuropsychiatric illness and these centrally placed mediators of signaling comes from exploration of dopamine neurotransmission (Fig. 72–1). Scaffolding proteins, the β -arrestins, are traditionally associated with the termination of G protein–coupled receptor (GPCR) signaling and desensitization. After a receptor is stimulated, GPCRs are phosphorylated, leading to the β -arrestin recruitment that uncouples the receptor from the G protein and leads to GPCR internalization. β -Arrestins also act as scaffolds for the formation of a protein complex that allows for GPCRs to signal independently from G proteins.^{22,24,26,71} Dopaminergic neurotransmission through GPCRs is mediated through a complex that involves Akt, β -arrestin 2 (β Arr2), and protein phosphatase 2A (PP2A). Akt is a serine/threonine kinase that is additionally regulated through phosphatidylinositol-mediated signaling.²⁵ Akt activity results from an equilibrium between phosphorylation (activation) and dephosphorylation (inactivation).²⁷ Regulation of GSK-3 β activity is achieved through phosphorylation of its N-terminal serine residue, leading to inhibition.¹¹⁸ The Akt- β Arr2-PP2A complex, when activated, dephosphorylates (deactivates) Akt, which leads to the activation of GSK-3 β through loss of inhibition (loss of phosphorylation).^{25,27,70}

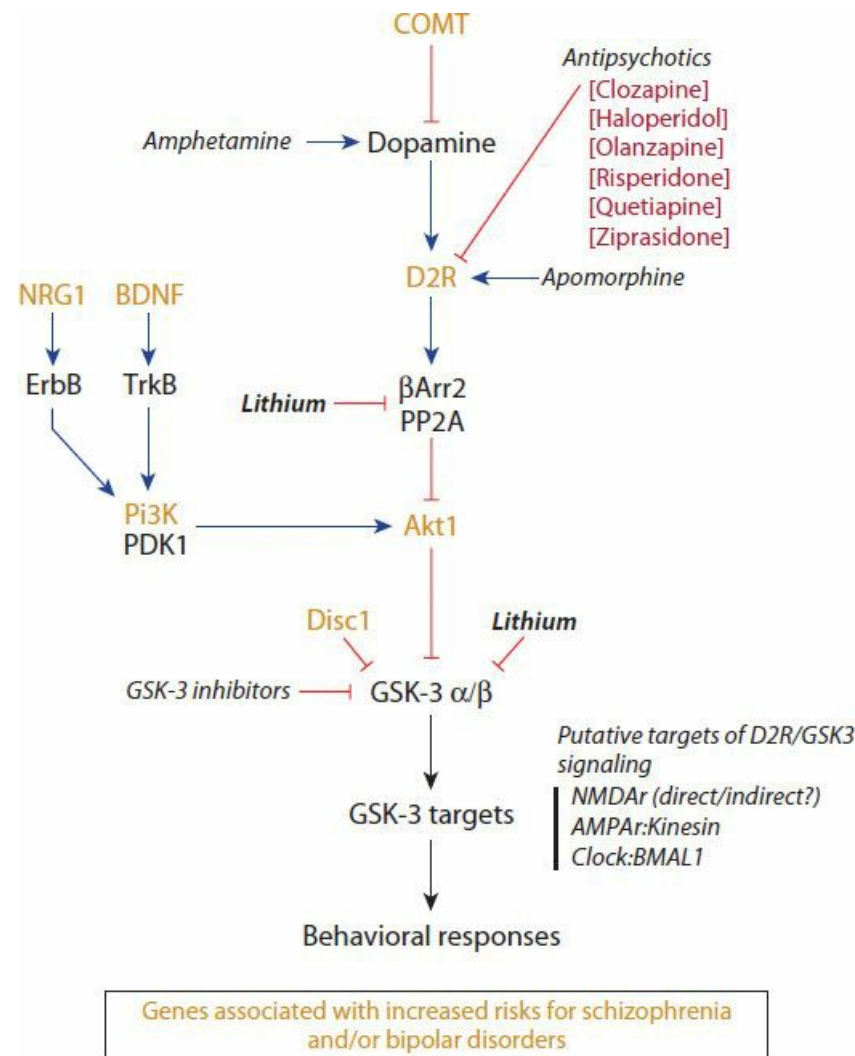

FIGURE 72–1. Regulation of Akt/GSK-3 signaling by psychoactive drugs and related network of gene products associated with mental disorders. Proteins labeled in orange are the product of genes associated with an increased risk of developing schizophrenia and/or bipolar disorders. Blue arrows indicate activation, and the red T-arrows indicate inhibition. Black arrows indicate actions that can either activate or inhibit the function of specific substrates. Behavioral changes in dopaminergic responses have been reported in Akt1 and β -arrestin 2 knock out mice and in GSK-3 β -HET mice. Akt = GSK-3 β modifying enzyme; COMT = catechol-O-methyltransferase; D2R = D₂ dopamine receptor; Disc1 = Disrupted-in-Schizophrenia 1; GSK-3 = glycogen synthase kinase 3; NRG1 = neuregulin 1; PDK1 = phosphatidylinositol-dependent kinase 1; Pi3K = phosphatidylinositol 3-kinase. (Adapted with permission from Beaulieu JM, Gainetdinov RR: The physiology, signaling, and pharmacology of dopamine receptors. *Pharmacol Rev.* 2011;63:182–217.)

Lithium is a direct inhibitor of GSK-3 β that can also inhibit its activity indirectly through a mechanism involving Akt activation.^{26,27,48,101} Lithium activates Akt by disrupting assembly of the Akt- β Arr2-PP2A complex through displacement of the magnesium cofactor required for assembly.^{25–27} Through disruption of this complex, which normally promotes Akt inactivation, lithium promotes Akt activation, leading to increased phosphorylation (inactivation) of GSK-3 β . This is demonstrated in β -arrestin knockout mice, which, unable to create this complex, are resistant to the behavioral effects of lithium.^{25,27,70,101}

Identification of the Akt- β Arr2-PP2A signaling complex as a target of lithium lends credence to the use of lithium as an adjunct to enhance the action of atypical antipsychotics and antidepressants in poorly responsive subjects by acting through Akt-GSK-3 β signaling.^{25,27,101}

Inhibition of GSK-3 β by lithium is thought to be neuroprotective by modifying the downstream targets and effectors of GSK-3 β activity.^{5,23,27,70,91,110,150,162} Lithium is implicated in the neuroprotective modulation of the bcl-2 gene, which is known for its role in preventing apoptosis and in downregulation of the proapoptotic protein p53. Lithium increases bcl-2 concentrations in cultured nervous tissue of both rats and humans.^{49,129} Additional support comes from patients undergoing long-term therapy with either lithium or valproic acid (VPA) who show prefrontal cortex volumes significantly greater than in patients not treated with either agent, suggesting a protective effect in humans.^{47,162} Further evidence points toward a neuroprotective and neurotrophic effect of lithium with evidence to support benefit in such diverse neurodegenerative conditions as Parkinson disease (in a mice model of Parkinson disease using N-methyl-4-pheynyl-1,2,3,6-tetrahydropyridine {MPTP}),¹⁹⁸ Huntington disease,¹⁶⁸ amyotrophic lateral sclerosis (ALS),⁶⁸ stroke and multiple sclerosis,^{23,47} traumatic brain injury,¹⁹⁹ and Alzheimer disease.^{5,19,22,25,42,131,136}

It would be naïve to assume that lithium has a single mechanism of action, and it is plausible that other mechanisms, such as the inhibition of inositol monophosphatases, also contribute to its pleiotropic effects on behavior. Compelling evidence has bridged a link between the current molecular targets and downstream regulators of the effects of lithium with the classic proposed mechanism of action, the inositol-depletion hypothesis.

Among the first proposed mechanisms of action of lithium was the inositol-depletion hypothesis.⁹⁰ Inositol is a six-carbon sugar that forms the backbone of a number of cellular signaling mechanisms. Lithium treatment results in a decreased myo-inositol (the most biologically active stereoisomer of inositol) concentration in the cerebral cortex.^{34,90,131} Abnormalities in regional brain myo-inositol concentrations are thought to occur in bipolar patients. This theory is partially supported by experimental magnetic resonance spectroscopy data.^{173,197} Myo-inositol is phosphorylated to form phosphatidyl inositol (PIP), which is further phosphorylated and combined with diacylglycerol (DAG) to form phosphatidyl 4,5-bisphosphate (PIP₂). Upon stimulation of a cell, G protein-coupled receptors activate phospholipase C (PLC), which hydrolyzes PIP₂ to release the secondary messengers DAG and inositol 1,4,5-trisphosphate (IP₃).^{34,92} Each of these secondary messengers in turn initiates a cascade of events, including activation of protein kinase C, which is important for calcium homeostasis and neurotransmitter release,^{131,173} as well as independent mobilization and regulation of intracellular calcium.^{149,162,173} Many extracellular signals, including some serotonin receptor subtypes, neurotrophin signaling pathways, receptor tyrosine kinase pathways, and G protein-mediated signaling, activate PLC to exert their actions.^{80,154,155}

Serial dephosphorylation of IP₃ leads to regeneration of myo-inositol and recycling of the inositol pool. Two enzymes involved in this pathway are inhibited by lithium. The first enzyme, inositol 1,4-bisphosphate 1-phosphatase (IPPase), dephosphorylates the bisphosphate to inositol monophosphate (IMP). The second enzyme, inositol 1-monophosphatase (IMPase), dephosphorylates IMP to myo-inositol⁴ (Fig. 72–2).

FIGURE 72–2. The actions of lithium on inositol depletion and autophagy induction. Extracellular signal binding to its cell surface receptor, either G protein-coupled receptor (GPCR) or RTK, activates phospholipase C (PLC), which hydrolyzes the phospholipid phosphatidyl bisphosphate (PIP₂) to yield second messengers inositol triphosphate (IP₃) and diacylglycerol (DAG). IP₃ is recycled by enzymes inositol bisphosphate phosphatase (IPPase) and inositol monophosphatase (IMPase) and converted to inositol (mainly myo-inositol), which is required for PIP₂ resynthesis. Lithium decreases intracellular inositol levels by directly inhibiting IPPase, IMPase, and myo-inositol transporter (MIT) that uptakes extracellular inositol. Decreased intracellular inositol levels are expected to subsequently reduce PIP₂ and prevent the formation of IP₃ and DAG, thus blocking transmembrane signaling and triggering the induction of autophagy. Lines with solid arrows represent stimulatory connections; lines with flattened ends represent inhibitory connections. Dashed lines represent pathways with reduced activity as a result of lithium treatment. IP = inositol monophosphate; IP₂ = inositol bisphosphate. (Adapted with permission from Chiu CT, Chuang DM: Molecular actions and therapeutic potential of lithium in preclinical and clinical studies of CNS disorders. *Pharmacol Ther.* 2010;128:281–304.)

The inhibition of IMPase is interesting and important. Lithium inhibits IMPase by “uncompetitively” binding to the enzyme-substrate complex and preventing the release of phosphate. It performs this function by displacing a magnesium ion from the active site after hydrolysis. This is the same mechanism by which lithium directly inhibits GSK-3β.⁴⁸ Uncompetitive refers to the inhibitor binding to the enzyme-substrate complex; the higher the concentration of the substrate, the more the enzyme is inhibited.^{70,86,127} Uncompetitive inhibitors only bind to the enzyme-substrate complex, inhibiting the reaction at that point. Uncompetitive inhibitor kinetics are related proportionally to the concentration of the enzyme–

substrate complex and cannot be overcome by increasing the concentration of the substrate, unlike a competitive inhibitor.¹⁵⁰ This supports a theory about the pathophysiology of bipolar disorder involving an excess of myoinositol and is one reason why the mood-stabilizing effects of lithium are thought to occur only in bipolar patients.⁹⁰ The nature of the action of lithium serves as a regulator to preferentially block pathologic signaling caused by excessive myoinositol while leaving the normal signaling intact. As described, IMPase is an important step in the cellular recycling of the inositol pool and is inhibited by lithium.

Myoinositol is also generated de novo from glucose-6-phosphate by inositol synthase, which forms IMP. The inhibition of IMPase by lithium subsequently leads to myoinositol depletion by preventing the conversion of the newly synthesized IMP to myoinositol. Interestingly, VPA also inhibits inositol synthase, illustrating a potential mechanism for the synergy of these complementary mood stabilizers.^{60,115} A third mechanism of intracellular diminution of inositol by lithium (as well as VPA and carbamazepine) is the effect of lithium on reducing activity and transcription of the sodium myoinositol transporter, preventing the uptake of exogenous myoinositol by the cell. This mechanism of inhibition may be overcome by increased extracellular concentration of myoinositol.⁹⁰

The result of these effects is depletion of the inositol pool available to the cell, causing a series of events at different points in the signal transduction cascade that leads to differential gene transcription and expression. This sequence ultimately is responsible for some of the observed clinical effects of lithium on the central nervous system (CNS).¹⁷⁰ Experimental data using dextroamphetamine as a model for clinical mania demonstrate increased regional inositol signaling in the human brain that is attenuated by pretreatment with lithium, lending support to the hypothesis.³¹

The inositol depletion hypothesis, while an original attempt to explain in molecular terms the therapeutic effects of lithium, does not fully elucidate nor replicate the clinical disease or response to therapy. In vivo studies with more drastic inositol depletion than that which occurs from lithium therapy fail to replicate predicted behavioral patterns. Studies in knockout mice lacking various isoforms of inositol monophosphatase fail to replicate the antidepressant or antimanic effects of lithium. The model remains an attractive one, and the flaws may represent species variation with validity more in humans with bipolar disorder than the mouse model illustrates.^{23,131,169} However, there may be a synergy with other proposed mechanisms of lithium's effect. Using a yeast model, it was shown that GSK-3 β is required for de novo inositol synthesis, and that loss of GSK-3 β activity leads to inositol depletion. This finding links the two targets of not only lithium, but other mood stabilizing pharmaceuticals.¹²

In summary, although the precise mechanism of action is unknown, some common features of investigation have emerged. The potential targets, widely found and disparate in function, all seem to be inhibited by lithium in an uncompetitive fashion, most commonly through displacement of a divalent cation, usually Mg²⁺. The systems affected by this inhibition vary widely. Downstream targets seem to modulate secondary cell messengers and intracellular signal transduction, transcription factors and gene expression, and neuronal plasticity and cellular differentiation. Further study is needed to elucidate the complex interaction of these pathways with the action of lithium to form an integrated hypothesis.

PHARMACOKINETICS AND TOXICOKINETICS

The volume of distribution of lithium is between 0.6 and 0.9 L/kg. It has no discernible protein binding and distributes freely in total body water, with the exception of the cerebrospinal fluid (CSF), from which it is actively extruded.^{62,81,163} The extrusion is believed to occur through an active transport process involving sodium/lithium exchange at the arachnoid processes.⁵⁹ The immediate-release preparations of lithium are rapidly absorbed from the gastrointestinal (GI) tract. Peak serum concentrations are achieved within 1 to 2 hours. Sustained-release products demonstrate variable absorption, with a delay to peak of 4 to 5 hours.^{81,182} In overdose, a longer delay to reach peak concentrations or multiple peaks may occur.^{58,812} Chronic therapy prolongs the elimination of lithium, as does advancing age.⁸¹ Although lithium is rapidly absorbed, tissue distribution is a complex phenomenon, with a significant delay in reaching a steady state. Lithium exhibits preferential uptake into the kidney, thyroid, bone, and other organs and tissues such as the liver and muscle. Lithium distribution into the brain can take up to 24 hours to reach equilibrium. Lithium is concentrated in red blood cells (RBCs) by both passive diffusion and active transport. The RBC concentration may correlate closely with the brain concentration, although this does not appear to be clinically useful.⁴³ The pharmacokinetic profile of lithium is described as an open, two-compartment model.^{62,81}

Each 300 mg lithium carbonate tablet contains 8.12 mEq of lithium.⁸¹ Ingestion of a single 300 mg tablet is expected to acutely increase the serum lithium concentration by approximately 0.1 to 0.3 mEq/L (assuming a volume of distribution of approximately 0.6–0.9 L/kg and a patient weight of 50–100 kg).

Lithium undergoes no metabolic transformation and is eliminated almost entirely (95%) by the kidneys, with a small amount eliminated in the feces.⁶² Lithium is also found in sweat, saliva, and breast milk.^{57,185} In an adult with normal kidney function, lithium clearance varies from 10 to 40 mL/min.^{81,181} At steady-state equilibrium, total body clearance equals renal clearance.

Lithium is handled by the kidneys much in the same way as sodium. Lithium is freely filtered, and more than 80% is reabsorbed by the proximal tubule. Evidence also indicates a small amount of reabsorption by the loop of Henle and distal tubule.^{36,69,112,181} Lithium excretion is therefore dependent on factors that affect the glomerular filtration rate (GFR) or decrease sodium concentration. Any condition that makes the kidney sodium avid such as volume depletion or salt restriction increases lithium reabsorption in the proximal tubule.^{82,181} Thus, risk factors for development of lithium toxicity include advanced age with its decrease in GFR; use of thiazide diuretics, nonsteroidal antiinflammatory drugs (NSAIDs), or angiotensin-converting enzyme (ACE) inhibitors; decreased sodium intake; and low-output heart failure.^{101,113}

The therapeutic index of lithium is narrow. The generally accepted steady-state therapeutic range of serum lithium concentrations is 0.6 to 1.0 mmol/L, although much disagreement exists about whether this serum concentration truly reflects therapeutic efficacy.^{81,121} Both in therapeutic and overdose situations, clinical signs and symptoms seem to be a more valuable indicator of brain lithium concentrations.^{17,140}

CLINICAL MANIFESTATIONS

Similar to other xenobiotics having prolonged redistributive phases and tissue burdens, lithium exposure can be divided into three main categories of toxicity: acute, acute-on-chronic, and chronic. In acute lithium toxicity, the patient has no body burden of lithium present at the time of ingestion. The toxicity that develops depends on the rates of absorption, distribution, and elimination. In chronic toxicity, the patient has a stable body burden of lithium as serum concentration is maintained in the therapeutic range, and then some factor disturbs this balance, either by enhancing absorption, or more commonly, decreasing elimination. For chronic users of lithium, small perturbations in the equilibrium between intake and elimination may lead to toxicity. In acute-on-chronic toxicity, the patient ingests an increased amount of lithium (intentionally or unintentionally) in the setting of a stable body burden. With tissue saturation, any additional lithium leads to signs and symptoms of toxicity.

Acute Toxicity

Acute ingestions of lithium-containing preparations produce clinical findings similar to that of ingestions of other metal salts, with predominant early GI symptoms. Nausea, vomiting, and diarrhea are prevalent. Significant volume losses may result from these symptoms. Patients may complain of lightheadedness and dizziness, and they may be orthostatic. Neurologic manifestations are a late finding in acute toxicity as the lithium redistributes slowly into the CNS.

Chronic Toxicity

Lithium is primarily a neurotoxin. The earliest case reports of lithium toxicity described predominantly neurologic symptoms.^{175,187} Most importantly, neurotoxicity does not correlate with serum concentrations. The initial clinical condition of the patient and the duration of exposure to an elevated concentration seem to be more closely predictive of outcome than the initial serum lithium concentration.^{3,9,88,167}

The tremor of lithium is likely one of the most commonly encountered drug-induced tremors in clinical practice, with approximately 27% of patients developing it.¹⁴¹ The tremor can diminish over time but may increase with toxicity. Other findings of chronic toxicity include fasciculations, hyperreflexia, choreoathetoid movements, clonus, dysarthria, nystagmus, and ataxia.¹⁸² Mental status is often altered and may progress from confusion to stupor, coma, and seizures.^{121,134} Electroencephalographic changes are most frequently reported as “slowing.”¹⁷¹ The progression of these symptoms follows no order, and any patient undergoing chronic therapy may have one or any combination of these features.

The syndrome of irreversible lithium-effectuated neurotoxicity (SILENT) is a descriptive syndrome of the irreversible neurologic and neuropsychiatric sequelae of lithium toxicity.^{3,97,151} SILENT is defined as neurologic dysfunction that is caused by lithium in the absence of prior neurologic illness and persists for at least 2 months after cessation of the drug. Case reports support these findings and this definition. However, as is true in most case reports, confounders make wide applicability of the findings difficult. Because of the polypharmacy prevalent in psychiatry, long-term neurologic sequelae attributed to lithium are frequently described in patients using lithium in combination with other xenobiotics, such as haloperidol, chlorpromazine, carbamazepine, phenytoin, aspirin, VPA, amitriptyline, β -adrenergic antagonists, calcium channel blockers, ACE inhibitors, diuretics, and NSAIDs.^{3,65,89,128,138} However, there exist reports of patients using lithium without coingestants and no comorbid illness who sustained lasting dysfunction as a result of lithium toxicity.^{9,105,145,167} Cerebellar findings seem to predominate in patients with SILENT.^{1–3,130,151} One of the predictors of persistent neurologic dysfunction may be the concomitant finding of hyperpyrexia, an ominous finding in patients with lithium toxicity.^{83,130} The mechanism of the persistent dysfunction is unclear, but demyelination and cellular loss are proposed.^{3,130,165}

Acute-on-Chronic Toxicity

Patients undergoing chronic therapy who acutely ingest an additional amount of lithium (either intentionally or unintentionally) are at risk for signs and symptoms of both acute and chronic toxicity. These patients may display prominent GI and neurologic symptoms and may be difficult to diagnose and manage. Serum lithium concentrations in cases of acute or chronic toxicity may be difficult to interpret, and therapy should be guided by the clinical status of the patient.

Other Systemic Manifestations of Chronic Lithium Therapy

The most common adverse effect of chronic lithium therapy is nephrogenic diabetes insipidus which can develop within weeks of the initiation of therapy and affects up to 40% of patients (Chap. 19).^{85,144}

Lithium inhibits the transport of sodium through the amiloride-sensitive epithelial Na⁺ channel (ENaC), which is also the main route of entry for lithium. Lithium has a twofold higher affinity than sodium for entry through this channel, without a corresponding means of extrusion and thus becomes concentrated intracellularly.^{106,181,182}

Lithium is believed to inhibit magnesium-dependent G proteins that activate vasopressin-sensitive adenylate cyclase, leading to decreased generation of cAMP in the cell membranes of distal tubular cells.^{35,50,180,186}

Decreased cAMP leads to reduced expression and translocation of the vasopressin-regulated water channel aquaporin-2 (AQP2), making the distal tubules resistant to the action of vasopressin, and thus unable to make a concentrated urine.^{6,35,120,188} Additionally, there is potential mechanistic overlap with GSK-3 β . GSK-3 β exhibits tonic inhibition of cyclooxygenase-2 (COX-2). With GSK-3 β inhibition by lithium, this inhibition is removed and increased COX-2 activity leads to increased prostaglandin expression in the renal medulla. Increased prostaglandin expression is important in nephrogenic diabetes insipidus through regulation of glomerular blood flow,^{156,157} as well as increasing the degradation of AQP2, further decreasing the ability to form a concentrated urine.^{106,107,156,157}

Chronic lithium therapy is also associated with chronic tubulointerstitial nephropathy, as manifested by the development of renal insufficiency with little or no proteinuria and biopsy findings of tubular cysts. This association was demonstrated in a biopsy-based study of 24 chronically treated patients, although the overall prevalence of this condition is low.⁸⁵

Lithium is associated with a number of endocrine disorders. The most prevalent endocrine manifestation of chronic lithium therapy is hypothyroidism.³⁹ The etiology is multifactorial. Lithium is selectively concentrated in the thyroid gland and competes for iodide transport, synthesis of triiodothyronine (T₃), responsiveness of the gland to thyroid-stimulating hormone (TSH), release of T₃ and tetraiodothyronine (T₄), and peripheral conversion of T₄ to T₃.^{39,73} Additionally, lithium decreases responsiveness of peripheral tissues to T₃ and increases antithyroglobulin antibodies if already present, it does not induce development de novo (Fig. 56–1).^{13,110,143} Although hypothyroidism is most common, hyperthyroidism and frank thyrotoxicosis are also reported.^{33,41,110} However, hyperthyroidism, by altering proximal tubule function, leads to decreased lithium excretion.²⁰ Thus, hyperthyroidism may lead to chronic lithium toxicity through impaired elimination, and the elevated lithium concentrations may mask the manifestations of hyperthyroidism.^{18,143}

The combination of hyperparathyroidism and hypercalcemia is frequently reported with chronic lithium therapy, most commonly in older women. The mechanism is thought to be modification of calcium feedback on parathyroid hormone release through alteration of a calcium-sensing receptor that prevents suppression of parathyroid hormone release in response to elevated calcium,¹⁵⁹ although stimulation of parathyroid hormone release, parathyroid gland hyperplasia, and adenomas are alternative suggested mechanisms.^{11,114,132,178}

Lithium is associated with a number of electrocardiographic (ECG) abnormalities, although the evidence for significant toxicity is lacking. Most reports are uncontrolled case reports without corroborating experimental data or biologic plausibility. The most commonly reported manifestation has been T-wave flattening or inversion, primarily in the precordial leads,¹⁴⁷ although prolongation of the QT interval is also noted.^{109,184,192} One study associated elevated serum lithium concentrations with QT prolongation above 440 msec, although the number of patients studied was small.⁹⁶ Associations have been made between lithium and sinoatrial dysfunction, with resultant bradycardia.^{10,77,146,172,179} However, many of these cases had either electrolyte disturbances or multiple other cardioactive xenobiotics involved that would be more likely causative.^{44,172,179,189} Numerous case reports have linked lithium with an ECG pattern that is consistent with a myocardial infarction, without evidence of biochemical markers of injury.^{104,152} Lithium blocks cardiac sodium channels in a transfected Chinese hamster ovary cell. This is the putative link between lithium therapy and the unmasking of a Brugada pattern as well as cardiomyopathy.^{7,46,55,193,196} For the most part, lithium has few consequential effects on cardiac function, even in overdose, and malignant dysrhythmias or significant dysfunction is very uncommon.

Developmentally, in utero exposure to lithium increases the incidence of congenital heart defects, specifically Ebstein anomaly.^{57,150,195} Additionally, many effects similar to those that occur in patients undergoing chronic therapy are found in infants exposed in utero, including thyroid disease and neurotoxicity.⁷⁵

Lithium causes a leukocytosis and an increase in neutrophils. It has been proposed as an adjunct to chemotherapy-

induced neutropenia, other marrow suppressive therapies, and acquired immunodeficiency syndrome (AIDS).⁵⁴ Although lithium increases the total neutrophil count, no improved clinical outcomes are documented, and its use has been superseded by recombinant colony-stimulating factors.^{66,150,160}

DIAGNOSTIC TESTING

Because of the prevalence of lithium use, therapeutic drug monitoring is readily available in most settings, and concentrations should be readily obtainable.¹⁹⁴ A lithium concentration should be requested upon patient presentation and serial measurements requested or considered in most instances, especially after ingestion of sustained-release preparations. Emphasis should be placed on the lithium concentration as a marker of exposure and response to therapy but not necessarily as a determinant of toxicity or treatment. The history, clinical signs, and symptoms rather than the absolute lithium concentration should guide therapy. The sample must be sent in an appropriate lithium-free tube, because use of lithiated-heparin tubes may lead to clinically false-positive results.¹¹³ Serum electrolyte concentrations and kidney function should be monitored because kidney function is important in determining the need for more aggressive therapy, including enhanced elimination techniques such as hemodialysis. If the patient is hypernatremic, nephrogenic diabetes insipidus should be suspected, and determinations of serum and urine osmolality and electrolytes help confirm the diagnosis ([Chap. 19](#)). If thyroid disease is suspected, thyroid function tests should be obtained. If a deliberate ingestion has occurred, a serum acetaminophen concentration should be obtained. An ECG is also indicated. The complete blood count may indicate a leukocytosis, as a stress response or due to the hematologic effects of lithium.

MANAGEMENT

The initial management and stabilization should begin with assessment and, if necessary, support of airway, breathing, and circulation. Lithium rarely, if ever, affects the patient's airway or breathing, although coingestants may. Emesis, which occurs with significant frequency after acute exposure, may lead to aspiration and respiratory compromise. After the patient is stable, the characteristics of the exposure should be determined while the physical examination and laboratory assessment commence. The formulation and nature of the product should be ascertained and most importantly, identified as immediate-release or sustained-release. Also, whether or not lithium is part of the patient's medication regimen may help determine whether the ingestion is acute, acute-on-chronic, or chronic.

Gastrointestinal Decontamination

For patients who present after an acute overdose or an acute-on-chronic overdose, a risk benefit analysis of GI decontamination must be undertaken. Two factors should be considered. With an acute overdose and predominance of early GI symptoms, including emesis, self-decontamination may already have started. Second, immediate-release preparations are often rapidly absorbed and may not lend themselves to GI evacuation.

Few GI decontamination options are available. Lithium is a monovalent cation that does not bind readily to activated charcoal.¹²³ Because of the danger of a depressed level of consciousness, potential loss of protective airway reflexes, and generally prominent emesis, no beneficial effect from activated charcoal is expected unless indicated for treatment of a potential coingestant. Induced emesis is no longer recommended. Orogastric lavage has essentially no role in the acute management of a patient with a lithium overdose unless indicated for a coingestant. Whereas immediate-release preparations of lithium are rapidly absorbed and typically produce emesis, sustained-release formulations of lithium (ie, controlled-release tablets) compounded in a slowly dissolving film-coated formulation often make the tablet too large to fit through even the largest lavage tube.

Sodium polystyrene sulfonate (SPS) is a cationic exchange resin often used for the treatment of severe hyperkalemia. It binds potassium in exchange for sodium, allowing elimination of excess potassium in the feces. Because of the similarity between potassium and lithium, use of SPS has been proposed for decontamination of patients being treated for lithium toxicity. A number of models have examined the effectiveness of this technique.¹²³⁻¹²⁵ Use of SPS has many theoretical benefits, including demonstrated effectiveness of lithium binding compared with activated charcoal and the ability of orally administered SPS to reduce serum concentrations of intravenously administered lithium in mice.¹²³ Unfortunately, the finding that doses used to increase lithium elimination also lead to significant hypokalemia in human subjects limits the application of this technique.¹⁶⁴ In a murine model, potassium supplementation with SPS was found to mitigate this process but only at the expense of elevating lithium concentrations.¹²⁵ Two reports in the literature demonstrate increased lithium elimination with SPS, one in a healthy volunteer and another in a patient with an acute overdose. However, the serum potassium concentration was not reported in either case.⁷⁴ In a retrospective cohort review of 12 chronically poisoned patients, it was suggested that SPS reduced the elimination half-life of lithium by 50%. However, many of the patients had altered kidney function that was corrected at the same time as the intervention (which was not standardized), and no clinical outcomes were reported.⁷⁶ At present, use of SPS in the management of the lithium-poisoned patient cannot be routinely

recommended, until further clinical trials can be performed.

Whole-bowel irrigation (WBI) is the only GI decontamination that has some demonstrated efficacy in eliminating lithium from volunteer human subjects. In one of the few clinical trials of WBI, the serum lithium concentrations of 10 normal volunteers who had ingested sustained-release lithium carbonate were plotted against time over a 72-hour period. In the second phase of the trial, when the volunteers received 2 L/h of polyethylene glycol solution one hour after the ingestion, there was a significant reduction (67%) in the serum concentration, even as early as one hour after the therapeutic intervention.¹⁷⁴ WBI is recommended for patients manifesting significant toxicity (ie, neurologic dysfunction) and who have ingested sustained-release preparations and have no contraindications (eg, protected airway, no obstruction or ileus) (Antidotes in Depth: A2).

Fluid and Electrolytes

The critical initial management of the lithium-poisoned patient should focus on restoration of intravascular volume, both in acute poisonings with GI losses and in chronic poisonings with toxic effects that are often the result of disturbances of kidney function and lithium elimination. Many patients with lithium toxicity have volume-responsive decreases in kidney function,¹⁵⁸ which can be managed by infusion of 0.9% sodium chloride solution at 1.5 to 2 times the maintenance rate. This therapy increases renal perfusion, increases the GFR, and lithium elimination. Urine output must be closely monitored and any electrolyte abnormalities corrected. Caution must be used in patients with prerenal acute kidney injury (AKI), chronic kidney disease (CKD), and congestive heart failure. Monitoring for the development of hypernatremia in patients suspected of having nephrogenic diabetes insipidus is critical.^{120,181,182}

Lithium-induced nephrogenic diabetes insipidus may be reversed by discontinuation of the drug and repletion of electrolytes and water. However, nonreversible effects are reported.^{106,181} Clinical application of amiloride to mitigate lithium-induced polyuria is described, although the potential for volume contraction and stimulation of lithium reabsorption limits recommendation of this drug as a routine adjunct to acute care.^{30,64,106,158}

Any attempt to enhance elimination of lithium by forced diuresis using loop diuretics (furosemide), osmotic agents (mannitol), carbonic anhydrase inhibitors (acetazolamide), or phosphodiesterase inhibitors (aminophylline) should be avoided. An initial small increase in elimination may be achieved, but typically salt and water depletion subsequently develop followed by increased lithium retention. Sodium bicarbonate for urinary alkalization should also be avoided because it does not significantly increase elimination over volume expansion with sodium chloride and may lead to hypokalemia, alkalemia, and fluid overload.

Extracorporeal Drug Removal

Debate surrounds the efficacy and practicality of using enhanced elimination techniques in cases of lithium poisoning. Lithium does have pharmacokinetic properties that make it amenable to extracorporeal removal,^{21,63,95,100,112} and with these characteristics, it would seem to be an ideal candidate for hemodialysis. In fact, hemodialysis is often recommended for treatment of acute, acute-on-chronic, and chronic lithium toxicity.^{14,63,98,148,182,199} However, some characteristics of lithium make extracorporeal elimination difficult. Lithium is predominantly localized intracellularly and diffuses slowly across cell membranes.⁶³ When traditional intermittent hemodialysis is used for chronic exposures, clearance of the blood compartment is often followed by a rebound phenomenon of redistribution from tissue stores, leading to recurrent increased serum concentrations. The clinical significance of this rebound is uncertain, but without additional elimination this can redistribute back into target tissues.³⁸ There have only been three cases reported of clinical deterioration after rebound from an extracorporeal elimination method, likely as a result of failed decontamination in an extended release ingestion.^{37,40,71} An additional complicating factor is that the brain, the “target organ” of toxicity, is not amenable to a rapid artificial elimination process. Attempts have been made to correlate the serum concentration with the lithium concentration in the CSF and brain. But in the few studies where CSF concentrations were obtained, although serum and CSF lithium concentrations seemed to correlate, brain concentrations and toxicity did not.^{92,99} Magnetic resonance spectroscopy studies of bipolar patients with steady-state lithium concentrations demonstrated a significant variability between brain and serum concentrations, especially within the therapeutic range.⁶⁷ In addition, because of the toxicokinetic profile of lithium, serum concentrations do not correlate well with toxicity.^{81,99,182}

Some consensus is emerging regarding when to perform an extracorporeal elimination technique (extracorporeal treatment {ECTR}). The Extracorporeal Treatments in Poisoning Workgroup (ExTRIP) has performed an extensive analysis of the data available regarding lithium. Their most recent consensus provides the following analysis: “ECTR should be performed in severe Li poisoning,” graded (1, D). The “1” indicates that more than 85% of their members strongly recommend, and the D that there is a very low level of evidence (no observational studies or randomized controlled trials).⁶¹ Hemodialysis or an alternative extracorporeal technique is clearly indicated for three groups of patients. The first group consists of patients who are manifesting severe signs and symptoms of neurotoxicity, such as alterations in mental status or seizures. The second group consists of patients who have AKI or CKD and show signs or

symptoms of lithium toxicity. Such patients are unable to eliminate their lithium burden on their own and should undergo hemodialysis. The third group consists of patients who show little or no sign of toxicity but who cannot tolerate sodium repletion therapy; these patients who should be considered for early hemodialysis include those with congestive heart failure or such “redistributive diseases” as liver failure, pancreatitis, or sepsis.

For a patient who belongs to this last group, the next step is to determine the probability that the patient will develop toxicity if elimination is not enhanced. The criteria for hemodialysis originated from a case series of 23 patients and a review of 100 other patients published in 1978, which was before the introduction of sustained-release products.⁸⁸ These recommendations have never been prospectively evaluated (or subsequently reevaluated).^{15,63,72} The ExTRIP group proposes the consensus recommendations based on the classification of the overdose and categories based on serum concentrations⁶¹ (Table 72–1).

TABLE 72–1. Consensus Recommendations for Hemodialysis

<i>Characterization</i>	<i>Reasonable</i>	<i>Suggested</i>	<i>Recommended</i>
Acute with normal GFR	>2.5 mEq/L	>4.0 mEq/L	>6.0 mEq/L
Chronic with normal GFR	>2.5 mEq/L	>3.5 mEq/L	>5.0 mEq/L
Acute or chronic with kidney disease (GFR <60 mL/min)	>2.0 mEq/L	>2.5 mEq/L	>3.0 mEq/L

GFR = glomerular filtration rate.

Interestingly, the above serum concentrations and recommendations are irrespective of symptomatology. Additional consensus recommends ECTR for acute neurologic dysfunction such as confusion, decreased level of consciousness, and seizures. It is also suggested to use ECTR for hyperthermia. Whether hemodialysis diminishes or enhances the risk of permanent neurologic sequelae is a subject of debate.^{176,177} Although no controlled studies have analyzed this important management question, the preponderance of evidence suggests a reduced risk.^{3,9,15,63,95,99,137,148,151,166,182}

Continuous venovenous hemodialysis and continuous venovenous hemodiafiltration are two continuous renal replacement therapies (CRRTs) commonly used in the treatment of patients with AKI or volume overload and for elimination of xenobiotics.^{14,29,183} Both techniques are effective in patients who are hemodynamically unstable because blood flow through the filter is pump driven and is not dependent on the arterial blood pressure.^{72,135} Other continuous techniques that use patient blood pressure as the basis of flow through the system also may have application here.¹⁸³ Traditional intermittent hemodialysis (IHD) offers clearance rates that vary between 50 and 170 mL/min with blood flows of 250 mL/min or more.^{63,126,148,183} Although CRRT techniques offer lower clearance per hour than does IHD, their overall daily clearances are similar.⁶³ With continued improvements in techniques, use of high volumes, and high dialysate flow rates, clearances are improving, approaching more than half the clearance per hour achieved by IHD in some studies.⁷³² One case of a rebound concentration was reported in a patient treated with continuous arteriovenous hemodiafiltration,³² and one case with use of combined renal replacement therapies, including venovenous techniques, showed no rebound.¹⁴ Unfortunately, CRRT requires prolonged anticoagulation with its inherent risks. Nevertheless, these techniques may be beneficial in patients who are hemodynamically unstable, or they may be used in series with traditional dialysis in other patients to prevent redistribution of lithium and rebound of serum concentrations (Chap. 10).

After an initial run of an ECTR such as IHD, repeat intermittent IHD should be continued until serum lithium concentrations are consistently below 1.0 mEq/L.

Peritoneal dialysis (PD) offers no increased efficacy of clearance of lithium over the natural clearance of normal kidneys.^{15,63} Although recommended in the past, given its lack of efficacy coupled with its infrequent use and potential for serious complications such as bowel perforation, PD has no role in the management of lithium-poisoned patients.

SUMMARY

- Lithium is a simple ion with extensive current usage and extremely varied and complex clinical and pathophysiologic effects.
- It is available in multiple formulations, both immediate release and sustained release, and has an essential role in clinical psychiatry.
- Because of the complexity of the pharmacokinetic profile of lithium, toxicity may develop in a wide range of conditions and may be precipitated by both intentional overdose and therapeutic misadventure.
- The care of lithium-poisoned patients should be predicated on rapid clinical evaluation of the condition of the patient

coupled with identification of the type of poisoning

- Management includes the use of volume resuscitation and WBI and hemodialysis or other extracorporeal techniques, when indicated, to prevent or treat severe neurologic morbidity and to prevent mortality.

73 MONOAMINE OXIDASE INHIBITORS

Alex F. Manini

HISTORY AND EPIDEMIOLOGY

Monoamine oxidase inhibitors (MAOIs) have a unique history, pharmacology, and toxic syndromes associated with their use. This drug class has fallen in and out of favor with scientists and clinicians over the last several decades. While toxicity from MAOI ingestion is becoming less common due to more limited clinical usage of the traditional nonselective MAOIs, an understanding of MAOI toxicity is fundamental to any clinician who takes care of patients with acute poisoning.

Monoamine oxidase (MAO) was discovered in 1928 and named by Zeller when the enzyme was recognized to be capable of metabolizing primary, secondary, and tertiary amines such as tyramine and norepinephrine.¹³¹ Subsequently, the “monoamine hypothesis” postulated depression as a monoamine deficiency state and MAOIs targeted monoamine metabolism for therapeutic benefit. In the early 1950s, iproniazid, a drug previously used to treat tuberculosis, was found to produce favorable behavioral adverse events. By the mid 1950s, it was demonstrated that iproniazid inhibited MAO, and it then became the first antidepressant used clinically.⁴⁶

In the late 1960s, two MAO isoforms were identified each with substrate and inhibitor specificity. This determination led to the development of selective MAOIs in attempts to minimize the many food and drug interactions that occur with the traditional nonselective MAOIs. Nonselective MAOIs proved to be potent and efficient antidepressants and became first-line therapy for depression. In the 1970s, alternative therapies for depression, such as tricyclic antidepressants, were developed and achieved clinical success without as many food interactions.

Intentional MAOI overdose is relatively uncommon and accounts for a dwindling number of annual exposures reported to the American Association of Poison Control Centers. From 2000 to 2010 there was a decreasing trend in the number of exposures with only 228 exposures reported in 2010,¹⁶ representing less than 1% of all antidepressant exposures. Of the reported exposures in 2010, there were only five cases of “major toxic effect” (defined as life-threatening signs or symptoms) and no deaths were reported. Over the past two decades, annual reported MAOI exposures have decreased 34% since 1985 (Chap. 136). Global MAOI exposure rates declined in proportion with the United States, with the possible exception of exposures to moclobemide, a drug not approved by the US Food and Drug Administration (FDA).³³

PHARMACOLOGY

Chemistry

Monoamines, also known as biogenic amines, include the neurotransmitters norepinephrine, dopamine, and serotonin, which share the presence of a single amine group and the ability to be metabolized by MAO. Monoamine oxidase is a flavin-containing enzyme present on the outer mitochondrial membrane of central nervous system (CNS) neurons, hepatocytes, and platelets. In a two-step reaction, MAO catalyzes the oxidative deamination of its various substrates. The reaction liberates H_2O_2 , a reactive oxygen species. Deamination by MAO is one of two major routes of elimination of monoamines, the other being extracellular degradation by catechol-O-methyltransferase (COMT). Serotonin, which is not metabolized by COMT, is the exception to this rule.

Monoamine Neurotransmitter Stores

Monoamine neurotransmitter synthesis, vesicle transport, vesicle storage, uptake, and degradation are described in detail in Chap. 14. In the neuron, MAO functions as a “safety valve” to metabolize and inactivate any excess monoamine neurotransmitter molecules. Once monoamines reenter the cytoplasm from the synaptic cleft, they can either reenter vesicles for further storage and release, or can be rapidly enzymatically degraded by MAO.

MAO Isoforms

There are two MAO isoforms, each with their own substrate and inhibitor specificity (Table 73–1). MAO-A preferentially metabolizes norepinephrine and serotonin, and MAO-B preferentially metabolizes benzylamine in vitro. Both isoforms metabolize tyramine and dopamine with comparable efficiency, but they are localized to differing anatomic regions, with

MAO-A concentrated in the intestine and liver, whereas MAO-B is concentrated in the basal ganglia of the brain.²²

TABLE 73–1. Monoamine Oxidase (MAO) Isoforms: Substrate Affinities and Localization

	<i>MAO Isoforms</i>	
	<i>MAO-A</i>	<i>MAO-B</i>
Substrate affinity		
Dopamine	Moderate	Moderate
Epinephrine	Moderate	Moderate
Norepinephrine	High	Low
Serotonin	High	Low
Tyramine	Moderate	Moderate
Localization		
Brain	Low	High
Intestine	Moderate	Low
Liver	Moderate	Moderate
Placenta	High	Absent
Platelets	Absent	High

Mechanism of Action

MAOIs are transported into the neuron by the Na⁺-dependent membrane norepinephrine-reuptake transporter.⁷³ Inhibition of MAO prevents presynaptic degradation of monoamines, thus increasing the concentration of monoamine neurotransmitters available for synaptic storage and subsequent release (Fig. 73–1). Inhibition of MAO also results in indirect release of norepinephrine into the synapse, via displacement from presynaptic vesicles in a manner similar to amphetamines.¹¹⁶

FIGURE 73–1. Sympathetic nerve terminal. Dopamine is synthesized in the sympathetic nerve cell and transported into vesicles where it is converted to norepinephrine (NE) and stored in vesicles (●). An action potential causes the vesicles to migrate to and fuse with the presynaptic membrane. NE diffuses across the synaptic cleft and binds with and activates postsynaptic α and β -adrenergic receptors. Neuronal NE reuptake occurs via the monoamine transporter. NE is transported back into vesicles by the vesicular monoamine transporter (VMAT; inset) or metabolized to 3,4 dihydroxyphenyl acetic acid (DOPAC) by mitochondrial monoamine oxidase (MAO). NE that diffuses away from the synaptic cleft is inactivated by catechol-O-methyl transferase (COMT). AADC = aromatic L-amino acid decarboxylase; DBH = dopamine beta-hydroxylase; NET = NE transporter.

Elevated synaptic concentrations of serotonin are most closely correlated with the antidepressant therapeutic effects of MAOIs. The enzymatic inhibition produced by MAOIs precedes the clinical effects by as long as 2 weeks. This finding, which is similar to other antidepressants, may relate to the relatively slow downregulation of postsynaptic CNS serotonin receptors.⁹⁴

MAOIs impair norepinephrine synthesis due to dopamine- β -hydroxylase inhibition. Impaired norepinephrine synthesis leads to eventual depletion of norepinephrine stores. Additionally, indirect dopamine agonism occurs via elevated synaptic concentrations of dopamine. Dopamine agonism results in β -adrenergic stimulation, peripheral vasodilation, and direct α -adrenergic stimulation at high doses.

The hydrazide MAOIs (eg, phenelzine, isocarboxazid) are thought to be cleaved to liberate pharmacologically active products (eg, hydrazides), which are cleared by acetylation in the liver.

First-Generation MAOIs: Nonselective and Irreversible

Monoamine oxidase inhibitors are a chemically heterogeneous group of xenobiotics (Fig. 73–2). First-generation MAOIs

(ie, irreversible and nonselective) in clinical use include the reactive hydrazide derivatives (phenelzine, isocarboxazid) and an amphetamine derivative (tranylcypromine).⁴⁵ First-generation MAOIs bind covalently to MAO and irreversibly inhibit the function of the enzyme. Thus, patients taking these MAOIs are depleted of the enzyme until new MAO is synthesized, a process that typically takes up to 3 weeks. Patients taking first-generation MAOIs remain at risk for food and xenobiotic interactions during much of this period. Because nonselective MAOIs inhibit both isoforms of MAO (ie, MAO-A and MAO-B), inhibition of intestinal and hepatic degradation of biogenic amines occurs. As a result, patients who receive these xenobiotics must be placed on a restrictive diet to prevent adverse events resulting from the absorption of undigested tyramine from the gut.

FIGURE 73–2. Structural similarities between amphetamine and the MAOIs. The words in parentheses are the chemical classes of the monoamine oxidase inhibitor (MAOI).

Phenelzine, isocarboxazid, and tranylcypromine are currently FDA approved for treatment of refractory depression.^{58,77} Pargyline, previously approved for use as an antihypertensive due to decreased peripheral vascular resistance, is no longer routinely used.¹²⁶ Phentermine is a nonselective MAOI, which is prescribed for the short term treatment of obesity.¹²²

Other enzyme systems inhibited by first-generation MAOIs include amine oxidases such as diamine oxidase and semicarbazide-sensitive oxidases, arylamine N-acetyltransferase (by tranylcypromine), ceruloplasmin, alcohol dehydrogenase (by tranylcypromine), dopa decarboxylase, L-glutamic acid decarboxylase, γ -aminobutyric acid (GABA) decarboxylase and GABA transaminase (by hydrazide MAOIs), alanine aminotransferase (by phenelzine), and other pyridoxine (B_6)-containing enzyme systems.⁴⁹ The clinical implications of inhibiting these diverse enzyme systems, other than alcohol dehydrogenase and cytochrome P450,¹⁰³ are poorly understood.

Second-Generation MAOIs: Selective and Irreversible

Selective MAOIs preferentially inhibit one of the two MAO isoforms, although isoform selectivity is lost as the dose is increased.

MAO-A Inhibitors. Clorgyline is an MAO-A inhibitor structurally related to pargyline. Once thought to be useful for treatment of depression, it has not found widespread use in psychiatry due to disappointing results from clinical trials. However, clorgyline is now being investigated in congestive heart failure and may see a future role in the treatment for those patients.

MAO-B Inhibitors. Selegiline is a selective MAO-B inhibitor that is FDA approved for the treatment of Parkinson disease,⁵⁸ although it does exhibit weak MAO-A inhibition at therapeutic doses.⁶⁸ Selegiline transdermal system is FDA approved for treatment of major depressive disorder in adults as an alternative to the traditional oral delivery system.^{6,58,98} Rasagiline is another MAO-B selective MAOI that is FDA approved to treat Parkinson disease.¹⁹

Third-Generation MAOIs: Selective and Reversible

Reversible inhibitors of monoamine oxidase-A (RIMAs) are a class of drugs that selectively and reversibly inhibit MAO-A.⁵⁸ These xenobiotics were developed in an effort to compensate for the limitations of first- and second-generation MAOIs (see Clinical Manifestations). RIMAs can be displaced by tyramine from the active site of the enzyme MAO-B, thereby enabling peripheral metabolism of the amine. Because tyramine is not present in high concentrations in the brain, MAO-A continues to be inhibited and the antidepressant effects are achieved.⁵⁸ Moclobemide is the most widely studied RIMA and is approved as an antidepressant in Europe and other parts of the world.³³ However, due to lack of financial incentives to gain approval, the drug is not currently available in the United States. Brofaromine and toloxatone are other RIMAs that were recently introduced but are less well studied.

Naturally Occurring MAOIs

The extract of the plant St. John wort (*Hypericum perforatum*) is licensed in Germany for use as an antidepressant. Although the major constituents, hypericin or hyperforin have weak MAOI activity, it is uncertain whether this activity is responsible for its antidepressant effect. However, MAOI activity explains sporadic reports of hypertensive crises, cardiovascular collapse during anesthesia, and serotonin toxicity associated with use of this herbal product.^{52,85}

Ayahuasca, a hallucinogenic beverage used by South American natives, is an ethnobotanical mixture of dimethyltryptamine and harmala alkaloids that circumvents gastrointestinal (GI) MAO. Dimethyltryptamine, which is a potent visual hallucinogen, is derived from several local plant species,²⁶ but is not orally bioavailable because of its first-pass metabolism by MAO.⁷⁴ When *Banisteriopsis caapi*, a plant containing the MAO-inhibiting harmala alkaloids, is mixed with dimethyltryptamine-containing plants, the bioavailability of this hallucinogenic amine is improved.^{74,75}

MAO-B activity in tobacco plants has prompted studies to find a link between the lower platelet MAO-B activity of smokers and their lower rate of Parkinson disease.¹⁸ This finding has led to interest in studying other MAO-B inhibitors for potential applications as neuroprotective xenobiotics.¹³⁰

Miscellaneous and Experimental MAOIs

Other xenobiotics with nonselective MAO inhibitory properties are used for purposes unrelated to MAO inhibition. Furazolidone is an antimicrobial used to treat protozoan-related diarrhea and bacterial enteritis. Procarbazine is a hydrazide derivative indicated as a chemotherapeutic for Hodgkin lymphoma and some brain tumors. Linezolid is an antibiotic that produces weak, nonselective MAO inhibition.^{29,112,120} Azure B, a metabolite of methylene blue, is a high-potency reversible inhibitor of monoamine oxidase.⁸⁶

Research is active for novel MAO combination xenobiotics that target multiple mechanistic approaches for the treatment of dementia and parkinsonism.²⁷ Ladostigil combines the cholinergic effects of a carbamate with the aminergic effects of MAO-B inhibition.¹⁰⁴ M30 is an actively researched xenobiotic that combines iron chelation and radical scavenger effects with irreversible, nonselective MAO inhibition.³⁵ Neither xenobiotic has been approved by the FDA.

PHARMACOKINETICS AND TOXICOKINETICS

Monoamine oxidase inhibitors are absorbed readily when given by mouth, and peak plasma concentrations are reached within 2 to 3 hours. Like other antidepressants, these xenobiotics are lipophilic and readily cross the blood-brain barrier. MAOIs are hepatically metabolized by both oxidation (various CYP450 isoenzymes, including CYP2D6 and CYP2C19) and acetylation (N-acetyltransferase), to metabolites that are excreted in the urine.⁸

Like the original MAOI, iproniazid, phenelzine and isocarboxazid are metabolized to hydrazides. The rate of metabolism of the hydrazide MAOIs is dependent on the N-acetyltransferase phenotype (ie, “acetylator status”) of the patient (ie, fast or slow). About one-half of the US population, but as low as 10% of Native Americans, have a recessive single gene trait that effects the N-acetyltransferase enzyme in the liver and contributes to exaggerated clinical effects despite standard therapeutic dosing or even mild overdose.

The clinical effects of MAOI inhibition occur rapidly and are usually maximal within a few days. First-generation (ie, irreversible) MAOIs have durations of effect that far surpass their pharmacologic half-lives, and recovery from their effects requires the synthesis of new enzyme over a period of up to 3 weeks (the “washout period” is a misnomer as the effective period is dependent on enzyme regeneration).¹¹⁷ Thus, when switching from one serotonergic (ie, MAOI, SSRI, cyclic antidepressant) to another, a sufficient time period of 2 to 3 weeks must be allowed to prevent an adverse drug interaction. Due to the long half-life of fluoxetine and its active metabolite, norfluoxetine, a time period of 5 weeks is recommended when switching from fluoxetine to an MAOI.

PATHOPHYSIOLOGY

As discussed above (see Mechanism of Action), MAOIs contribute to adrenergic stimulation via release of norepinephrine from sympathetic nerve terminals.⁶⁴ This phenomenon may lead to hyperadrenergic crises particularly in the presence of foods or xenobiotics that serve as substrates for, or enhancers of, monoamine formation, such as tyramine.⁶³ In addition, norepinephrine release combined with MAO inhibition may result in so-called “autopotential,” or synergistic sympathomimetic effects. Autopotential may be responsible for paradoxical or hypertensive reactions sometimes observed following therapeutic doses of MAOIs.^{5,23}

Hydrazide MAOIs (eg, phenelzine) inactivate pyridoxal 5' phosphate, the cofactor necessary for neuronal decarboxylation of glutamic acid to the inhibitory neurotransmitter GABA. In addition, hydrazides may complex with pyridoxine, the precursor of pyridoxal 5' phosphate, thus enhancing its urinary elimination and further inhibiting the formation of neuronal GABA.⁸⁴ Decreased availability of neuronal GABA leads to CNS excitation following overdose of hydrazide MAOIs (Chaps. 58 and 120).⁶¹

Impaired GABA_A activity may contribute to symptoms of CNS excitation such as seizures, which occur in MAOI overdose. In animal models, isocarboxazid and tranylcypromine directly inhibit GABA-mediated Cl⁻ influx at GABA_A receptors.¹¹³ The exact binding site of MAOIs on the GABA_A receptor complex is unknown. GABA effects appear to be most localized in the caudate-putamen and nucleus accumbens areas in one animal model.⁸⁴ Elevated neuronal glutamate concentrations due to MAOI effects may also synergistically enhance CNS excitation.¹⁰⁶

CLINICAL USES

Many authors recommend the prescription of nonselective MAOIs only for resistant or atypical depression with prominent neurovegetative symptoms.³⁰ However, selective and reversible MAOIs are the subject of renewed clinical applicability and basic science research interest. MAO-B selective xenobiotics, such as selegiline, are widely used for the treatment of Parkinson disease. Reversible inhibitors of MAO, such as moclobemide, are used in Europe for depression, phobias, anxiety, and other select indications.¹²⁹ Current applicability of a new generation of experimental MAOIs is being investigated as neuroprotective xenobiotics for a variety of neurodegenerative diseases.¹³⁰

HYPERADRENERGIC CRISIS

Hyperadrenergic crises may occur in patients with MAO-A inhibition when tyramine-containing foods such as aged cheeses and fermented drinks are eaten (Table 73–2).¹³⁰ Tyramine is an indirect-acting sympathomimetic amine with an amphetaminelike mechanism of action.¹³² The MAO-A present in the intestinal wall and liver extensively metabolizes dietary amines preventing them from entering the circulation, but in the presence of irreversible MAO-A inhibition this protective mechanism is lost, allowing tyramine and other dietary monoamines to enter the circulation.¹² This enzymatic failure results in an amphetaminelike induction of norepinephrine from peripheral adrenergic neurons and provocation of hyperadrenergic crisis. A meal that contains 6 to 8 mg of tyramine per serving can potentially precipitate this reaction, and ingestion of a total of 25 to 50 mg can produce a severe and possibly life-threatening reaction.^{28,118,124} A recent European study of biogenic amines contained in retail meat products (eg, sausage, cold cuts) found that such products contained up to 50 mg/kg tyramine which would pose a high risk for individuals receiving first-generation MAOI therapy.⁸² Additionally, despite compliance with diet, chronically elevated cytoplasmic and synaptic concentrations of norepinephrine due to therapeutic MAOI administration can lead to adrenergic crises in some patients. Dietary restrictions and recommendations for patients prescribed first-generation MAOIs are summarized in Table 73–2.^{28,118,124} As detailed above, a time period of 3 weeks is sufficient to allow a normal diet to be resumed.¹¹⁹

TABLE 73–2. Dietary Restrictions for Patients Taking MAOIs

<i>Low Tyramine Content</i> (0–4 mg/serving)	<i>Moderate Tyramine Content</i> (4–8 mg/serving)	<i>High Tyramine Content</i> (> 8 mg/serving)
Chocolate	Avocado/guacamole	Aged, mature cheeses
Cottage cheese, cream cheese, yogurt, sour cream	Banana peels or stewed whole bananas	Broad beans or fava beans
Distilled alcohol	Meat extracts	Fermented sausage
Nonoverripe fruit	Overripe fruit/figs	Liver
Soy sauce	Pasteurized light and pale beers	Red wines, selected beers
		Smoked, pickled, aged, putrefying meats or fish, caviar
		Yeast and meat extracts

Recommendation: Foods with *high* tyramine content should be avoided, those with *moderate* content should be consumed in restricted moderation, and those with *low* content may be cautiously consumed.

The clinical syndrome of tyramine-related hyperadrenergic crisis is characterized by hypertension, headache, flushing, diaphoresis, mydriasis, neuromuscular excitation, and potential cardiac dysrhythmias.¹²¹ This reaction is subjectively reported in up to 10% of patients taking MAOIs chronically,⁹² and can occur up to 3 weeks following discontinuation of the drug.¹²⁷ Monoamine oxidase inhibitors specific for the MAO-B isoform are less likely to predispose to food or drug interactions by maintaining significant hepatic MAO-A activity; however, isoform specificity is lost as dose is increased.

SEROTONIN TOXICITY

Any xenobiotic with serotonin-potentiating activity can interact with the MAOIs to produce serotonin toxicity. Combinations of xenobiotics commonly implicated in this reaction are involved with serotonin synthesis (eg, L-tryptophan), release (eg, amphetamines), agonism (eg, triptans metabolized by MAO), neuromodulation (eg, lithium), or reuptake inhibition (eg, selective serotonin reuptake inhibitors, meperidine, dextromethorphan). Animal studies have demonstrated that both meperidine¹⁰⁸ and dextromethorphan¹⁰⁹ administration can lead to fatal serotonin toxicity. Serotonin toxicity most commonly occurs in patients receiving combination therapy with two or more serotonergic agents; however, it may rarely occur with just one serotonergic agent.⁸³

Clinically, serotonin toxicity runs a spectrum of severity,¹³ and is described in detail in [Chap. 75](#). Minor findings can include akathisia, myoclonus, hyperreflexia, diaphoresis, penile erection, shivering, hyperactive bowel sounds, and tremor. Tremor and hyperreflexia are typically greater in the lower extremities. Shivering is classically described as similar to “wet dog shakes,”⁴³ and can occur at a range of body temperatures.⁸⁰ Severe signs and symptoms can include life-threatening autonomic instability, muscular rigidity, and hyperthermia.

Several diagnostic schemes for serotonin toxicity exist.^{13,24,47,93,114} However, the key diagnostic criterion is exposure to a serotonergic. Because no diagnostic test is yet available, the diagnosis of serotonin toxicity must be established on clinical grounds. The onset of clinical symptoms may occur within minutes after a change in medication or self-poisoning.⁶⁹ Most patients with serotonin toxicity develop symptoms within 6 hours. Key clinical features of MAOI-induced serotonin toxicity are summarized in [Table 73–3](#).

TABLE 73–3. Comparison of Clinical Manifestations Due to MAOI Toxicity

<i>Clinical Category</i>	<i>Hyperadrenergic Crisis</i>	<i>Serotonin Toxicity</i>	<i>MAOI Overdose</i>
Onset	Minutes to hours	Minutes to hours	≤ 24 hours
Duration	Hours	Hours	Days
Temperature	Normal	Elevated	Elevated
Neurologic	Headache, hemorrhagic stroke Neuromuscular excitation	Akathisia, hyperreflexia, shivering, tremor, seizures, autonomic instability, coma Myoclonus, "wet dog shakes," muscular rigidity	Neuropsychiatric effects, neuromuscular effects, headache, seizures Myoclonus, muscular rigidity
Cardiovascular	Hypertension, dysrhythmias, myocardial injury	Hypertension, hypotension, tachycardia, palpitations, dysrhythmias	Hypertension (early), hypotension (late), tachycardia, palpitations, dysrhythmias, myocardial injury
Gastrointestinal	Nausea	Hyperactive bowel sounds	Nausea, vomiting, diarrhea
Dermatologic	Flushing, diaphoresis	Diaphoresis	Flushing, piloerection, diaphoresis
Ophthalmologic	Mydriasis	Mydriasis	Mydriasis, ocular clonus

MAOI = monoamine oxidase inhibitor.

OVERDOSE

Monoamine oxidase inhibitor overdose may result in severe and life-threatening clinical manifestations, especially if the MAOI is a first-generation drug such as phenelzine. Classically, the clinical course involves a biphasic response characterized by initial CNS excitation and peripheral sympathetic stimulation that terminates in coma and cardiovascular collapse.⁶⁶ This biphasic model is hypothesized to result from an initial adrenergic crisis followed by inhibition of norepinephrine release,¹³² and is supported by animal studies.^{37,41} Additionally, depletion of norepinephrine stores may be partially or fully responsible for late hypotension observed in MAOI overdose. Toxic dose-response relationships in man are unclear, but overdose of 5 mg/kg of a first-generation MAOI is potentially life threatening.^{11,66} Clinical manifestations of MAOI overdose are summarized in [Table 73–3](#).

Patients with MAOI overdose are initially asymptomatic for several hours. Delays in clinical toxicity are well described.^{70,72,96} Unstudied hypotheses that might explain this phenomenon include all of the following: initial reversible binding to MAO, cumulative effects, time-dependent alterations to MAO substrate stores, individual acetylator status, and hydrolysis of the hydrazide MAOIs. While clinical toxicity should generally be apparent within the first several hours (initially with neuromuscular and sympathetic effects),⁶⁶ maximal toxicity may be delayed up to 24 hours after overdose.^{66,72,96}

Neurologic effects can be considered neuropsychiatric, neuromuscular, mental status alteration, seizures, and chronic effects. Neuropsychiatric effects include agitation, akathisia, and hallucinations. Neuromuscular effects include flailing and tremor of the extremities, nystagmus, opsoclonus, fasciculation, myoclonus, hypertonia, hyperreflexia, muscular irritability, and muscular rigidity, the latter of which may lead to secondary effects such as hyperthermia and rhabdomyolysis. Effects on mental status alteration include a variable spectrum from confusion to coma, the latter of which is a typically end-stage finding. Seizures may be either partial or generalized, and decorticate or decerebrate rigidity may alternate with periods of flaccid paralysis.

Severe hyperthermia (> 106°F) due to MAOI toxicity may have a multifactorial etiology and is an ominous sign.¹⁰⁷ Temperature dysregulation may be due to adrenergic crisis, muscular hypertonia, or CNS effects. Secondary effects from severe hyperthermia include disseminated intravascular coagulation and metabolic acidosis.⁷²

Cardiovascular effects follow the previously described initial hyperadrenergic crisis followed by cardiovascular collapse. Thus, initially, hypertension, tachycardia, palpitations, and tachydysrhythmias are to be expected.⁵⁵ In severe poisoning, late toxicity can include development of hypotension, reflex tachycardia or bradycardia, bradydysrhythmias, and sudden death.^{70,97} Alterations in myocardial supply/demand dynamics may lead to myocardial injury with elevations of serum cardiac biomarkers (eg, troponin I). Myonecrosis⁸⁸ and myocarditis¹²⁵ are also attributed to MAOI overdose.

Abnormalities on electrocardiography (ECG) may include ischemic changes on ECG (contiguous lead findings of T-wave inversion or ST-segment depression/elevation). Peaked T waves, in the presence⁶⁶ or absence⁹¹ of hyperkalemia, are also noted. Myocardial manifestations associated with catastrophic CNS processes (eg, intracranial hemorrhage) can also lead to T-wave inversions.

In addition to the effects mentioned above and listed in [Table 73–3](#), reported complications of MAOI overdose include acute kidney failure,^{66,70,88,97} fetal demise,⁹⁷ and hemolysis.^{66,72}

Selegiline Overdose

Selegiline is metabolized to L-methamphetamine, which may result in hypertension and tachycardia, even at therapeutic doses.^{1,7,101} Postmarketing surveillance safety data on the selegiline transdermal system demonstrated that only 13 (< 1%) out of 1516 patients studied reported a hypertensive event, none of which were objectively confirmed.⁸¹ Selegiline overdose produces hallucinations and convulsions and is associated with elevated urinary concentrations of L-methamphetamine and L-amphetamine.^{32,57}

Moclobemide Overdose

Moclobemide overdose typically produces mild to moderate CNS depression (drowsiness, disorientation), GI effects (nausea), and cardiovascular effects (tachycardia and mild hypertension).^{33,76} Serotonin toxicity due to the ingestion of moclobemide, alone⁵⁰ and in combination with other serotonergics^{78,87,123,128} is well described. In massive overdose, fatalities attributed solely to the toxic effects of moclobemide are reported.^{17,34,40}

OTHER ADVERSE DRUG REACTIONS

Clinically significant drug interactions with MAOIs can be due to serotonergic effects (see Serotonin Toxicity) and alterations to drug metabolism. Chronic use of phenelzine is also associated with an isoniazidlike peripheral neuropathy,⁴² possibly explained by pyridoxine deficiency.¹¹⁵ Administration of opioids with serotonergic properties (eg, meperidine, dextromethorphan) is absolutely contraindicated due to risk of precipitating the serotonin toxicity.^{13,39,100,108,109} Adverse drug reactions with other coadministered drugs that are metabolized by cytochrome P450 may be problematic, as first-generation MAOIs have an extensive inhibitory effect on CYP2C9, CYP2C19, and CYP2D6.^{8,103} Thus, barbiturates (eg, phenobarbital) and benzodiazepines (eg, diazepam, lorazepam) that are metabolized by hepatic cytochrome P450 may produce prolonged sedation and respiratory depression. [Table 73–4](#) summarizes analgesic safety in combination with MAOI drugs.³⁹

TABLE 73–4. Analgesic Safety When Combined with MAOIs

<i>Analgesic Class</i>	<i>Safe</i>	<i>Monitor Closely and Consider Alternative</i>	<i>Avoid Combination (Contraindicated)</i>
Nonprescription	Acetaminophen Aspirin Nonsteroidal antiinflammatory drugs		Dextromethorphan
Opioids	Buprenorphine Codeine Morphine Oxycodone	Propoxyphene	Meperidine Pentazocine
Nonopioids	Inhalational anesthetics Nitroglycerin	Barbiturates ^a Benzodiazepines ^a	Tramadol
Local anesthetics	Lidocaine		Cocaine

^aDrugs metabolized by hepatic cytochrome P450 may produce prolonged sedation and respiratory depression when combined with MAOIs. MAOI = monoamine oxidase inhibitor.

WITHDRAWAL REACTIONS

Monoamine oxidase inhibitor withdrawal may be severe, beginning 24 to 72 hours after discontinuation. Classically, MAOI withdrawal symptoms are the worst following discontinuation of high therapeutic doses of tranylcypromine and isocarboxazid.⁹ Symptoms range from nausea, vomiting, and malaise, to CNS symptoms such as agitation, psychosis, and convulsions. Treatment is generally supportive and typically involves a benzodiazepine such as diazepam and restarting the medication if clinically indicated.

DIAGNOSTIC TESTING

The clinical utility of therapeutic drug monitoring in the routine use of MAOIs is limited. Evaluation of MAO activity is not routinely available, requires a fresh specimen (preferably jejunal biopsy),⁶⁵ and is therefore not recommended. Experimental evidence suggests that inhibition of human platelet MAO-B activity by at least 85% may be associated with a favorable clinical antidepressant response to phenelzine.^{31,36}

Evaluation of MAOI toxicity remains a clinical diagnosis. Serum concentrations of MAOIs that correlate meaningfully with clinical effects are not well established. In addition, serum concentrations of any antidepressant, in general, can be misleading when obtained postmortem for forensic purposes.^{90,99} Hyperglycemia and leukocytosis may be present. Elevations in serum lactate concentrations and metabolic acidosis may be present from seizures, muscular hypertonia, or hyperthermia.

Measurement of blood and urinary concentrations of MAO substrates may provide indirect evidence of MAOI effects. MAOIs may cause increase serum serotonin, increase or decrease serum norepinephrine, increase urinary epinephrine and norepinephrine, and decrease urinary serotonin metabolites. Due to the indirect nature of this testing and the fact that its interpretation is fraught with confounding factors (eg, if the patient is receiving vasopressors), the routine measurement of serum and urinary MAO substrates is not recommended in the assessment of MAOI toxicity. Of note, patients taking selegiline¹⁰⁵ and tranylcypromine¹³³ may test positive for amphetamines on drug screens due to their metabolites.

MANAGEMENT

Out of Hospital

Decisions regarding referral to the emergency department (ED) must take into account factors such as patient age, intent of exposure, symptoms, as well as timing of exposure. All patients with MAOI exposures who display suicidal intent should be referred to an ED for evaluation. Children with exposure to even one adult formulation MAOI tablet or selegiline patch should be referred to the ED due to the potential for late-onset significant toxicity.³ Patients who exhibit more than mild headache or minimal diaphoresis following an acute MAOI ingestion should be referred to an ED. Observation at home is warranted in patients who are asymptomatic and more than 24 hours have elapsed since the time of ingestion. Due to

paucity of data at this time, patients with selegiline patch ingestion should be referred to the ED for observation, even if suicidal intent is absent.

Prehospital

Induction of emesis is not recommended.³ Activated charcoal can be administered to asymptomatic patients who have ingested overdoses of MAOI if no contraindications are present.² Transportation to the hospital should not be delayed in order to administer activated charcoal. Use of intravenous benzodiazepines for seizures and external cooling measures for severe hyperthermia ($> 106^{\circ}\text{F}$ [$> 41.1^{\circ}\text{C}$])¹⁰⁷ should be performed in consultation or authorization with medical direction from emergency medical services, by a written treatment protocol or policy, or with direct medical oversight.

Initial Approach in the Emergency Department

As with any serious ingestion, initial stabilization must include rapid assessment of the airway, breathing, and circulation as well as establishment of intravenous access, supplemental oxygen, and cardiac monitoring. Evidence of hyperthermia or hemodynamic instability following MAOI ingestion may be a manifestation of significant toxicity. Intravenous volume repletion should begin while gastrointestinal decontamination is considered. In any patient with altered mental status who will likely deteriorate progressively, early orotracheal intubation may facilitate safe gastric decontamination measures. Subsequent management should focus on stabilization of hyperthermia, seizures, and muscular rigidity.

Gastrointestinal Decontamination

Patients who overdose with MAOIs are more likely to benefit from gastrointestinal decontamination than most other overdose patients because of their high potential for morbidity and mortality.^{59,89} Orogastic lavage with a large bore orogastric tube (36–40 French) should be considered if a life-threatening ingestion is suspected to have occurred within several hours prior to presentation.^{39,59,89} Single-dose activated charcoal should be orally administered for ingestions presenting within several hours, unless contraindications are present. Whole bowel irrigation with oral polyethylene glycol electrolyte solution likely has limited utility unless there are coingestions with other sustained-release preparation medications. The lack of early clinical findings of poisoning should not dissuade the use of gastrointestinal decontamination given the potential for delayed clinical deterioration.

Cooling Measures

Severe hyperthermia must be treated with aggressive cooling. Use of ice baths (first choice for life-threatening hyperthermia),¹¹⁰ cold water, and fans are the mainstay of treatment (Chap. 30). There is no available evidence to support use of invasive cooling devices (ie, catheter based) or noninvasive devices such as cooling blankets. Indications for ice bath immersion to treat MAOI toxicity include rectal temperature greater than 106°F (41.1°C),¹⁰⁷ rigidity, and altered mental status. Benzodiazepines help control muscular rigidity, seizures, and agitation that may contribute to amelioration of hyperthermia and tachycardia. Patients with refractory hyperthermia despite the above measures may require neuromuscular blockade, using nondepolarizing paralytics, in conjunction with tracheal intubation and ventilation. The depolarizing paralytic succinylcholine should be avoided in severe MAOI toxicity due to the risk of precipitating lethal dysrhythmia due to hyperkalemia in the setting of rhabdomyolysis. Neuromuscular blockade eliminates hyperthermia that results from muscular rigidity, and can be employed if first-line treatments are unsuccessful. Antipyretics such as acetaminophen are unlikely to be efficacious because the hyperthermia is not due to alterations in the hypothalamic temperature set point.¹⁰⁷

Blood Pressure Control

Because there is characteristic fluctuation in vital signs associated with MAOI overdose, hemodynamic monitoring should be instituted even for patients who initially are stable. When supporting the patient's blood pressure, preference should be given to titratable drugs with a rapid onset and termination of action because of the potential for rapid hemodynamic changes. Use of β -adrenergic antagonists is contraindicated for control of hypertension in MAOI-related toxicity because the action of monoamines (eg, norepinephrine) at the neuronal synapse in the autonomic nervous system could result in refractory hypertension due to unopposed α -adrenergic agonism.⁹⁵

Patients who are normotensive at baseline and who experience MAOI-related severe hypertension can be treated with a short-acting α -adrenergic antagonist such as phentolamine (intravenous 2–5 mg) for effective control.¹² Other therapies such as nitroprusside and nitroglycerin may be preferred because they allow for titratable blood pressure control.²¹ Tyramine-related hypertensive crises can successfully be controlled with the dihydropyridine calcium channel blockers such as nifedipine and possibly the oral α -adrenergic antagonists such as terazosin but should be used with caution.^{20,48} Particular caution must be exercised in patients with baseline hypertension because overly aggressive blood pressure lowering may reduce cerebral perfusion pressure sufficiently to cause cerebral ischemia.

Patients who are hypotensive may require aggressive support with intravenous fluid resuscitation and vasopressors. Direct-acting sympathetic agents (eg, epinephrine, norepinephrine) can be used safely in patients taking MAOIs.¹⁴ Rather than causing release of a stored pool of norepinephrine, these xenobiotics bind directly with postsynaptic α - and β -adrenergic receptors.

Dopamine is contraindicated in hypotensive patients who have overdosed on MAOIs for several reasons. The indirect action of dopamine administration may produce a synergistic effect with MAOI, resulting in excessive adrenergic activity and exaggerated rises in blood pressure. In addition, most of the α -adrenoceptor mediated vasoconstriction of dopamine is secondary to norepinephrine release; in the presence of MAOIs, norepinephrine synthesis may be impaired from concomitant dopamine- β -hydroxylase inhibition, and dopamine may not reliably raise blood pressure if cytoplasmic and vesicular neuronal stores have been depleted. Finally, in the presence of impaired norepinephrine release or α -adrenergic blockade by any cause, unopposed dopamine-induced vasodilation from action on peripheral dopamine and β adrenoceptors may paradoxically lower blood pressure further.

Dysrhythmias

Due to the unique pharmacologic and toxicokinetic considerations of MAOI toxicity, adherence to advance cardiac life support protocols may not provide optimal results.⁴ In any stable patient, removal of the offending xenobiotic as well as correction of hypoxia, hypokalemia, and hypomagnesemia, if present, is a rational initial step.

Patients with immediately life-threatening dysrhythmias require rapid cardioversion. In the presence of the nonperfusing dysrhythmias such as ventricular fibrillation, pulseless ventricular tachycardia, and torsade de pointes unsynchronized electrical defibrillation is the treatment of choice.

Stable patients with ventricular tachycardia may benefit from a trial of antidysrhythmic drugs such as amiodarone or lidocaine. High-quality studies evaluating the use of these xenobiotics in the setting of MAOI overdose are not available.

Hemodynamically significant supraventricular tachycardia from MAOI toxicity should be corrected to prevent myocardial ischemia or infarction, ventricular dysrhythmia, and high-output heart failure. Benzodiazepines are safe and effective to treat sinus tachycardia, as long as respiratory status remains monitored. Adenosine and synchronized cardioversion are unlikely to be useful in the setting of ongoing presence of the MAOI, but may be considered in rare cases that are unresponsive to benzodiazepines. In patients with borderline hypotension, nondihydropyridine calcium-channel antagonists such as diltiazem and verapamil are relatively contraindicated because they may further lower blood pressure.

Hemodynamically significant bradycardia from MAOI toxicity may be refractory to standard advance cardiac life support protocols. An initial approach with intravenous fluid and atropine is a rational first-line therapy to temporize the patient with bradycardia and hypotension. Epinephrine and isoproterenol may also be administered while a pacemaker (transcutaneous or transvenous) is considered.

Management of CNS Manifestations

In acute altered mental status, hypoglycemia should be rapidly excluded.^{15,102} Mild to moderate CNS excitation may be treated with small incremental doses of parenteral diazepam. Seizures should be treated with benzodiazepines such as lorazepam in standard incremental doses. Empiric administration of pyridoxine (vitamin B₆), intravenously at 70 mg/kg, up to 5 g in adults should be considered in patients with status epilepticus, particularly following massive ingestions of hydrazide-derived MAOIs such as phenelzine which may deplete endogenous pyridoxine stores (Antidotes in Depth: A14).¹¹⁵ Theoretically, phenytoin is not likely to be useful for treatment of MAOI-induced seizures because there is no distinct seizure focus, but rather generalized neuronal dysfunction in the presence of MAOI (and metabolites) in the CNS.

Cyproheptadine

Cyproheptadine is a nonselective serotonin antagonist that is recommended as third-line therapy (after benzodiazepine administration and cooling measures) for MAOI-induced serotonin toxicity.¹³ Cyproheptadine prevents lethality in animal models of serotonin toxicity⁷⁹ and reportedly is beneficial in humans although its efficacy has not been rigorously established.^{38,44} It should be strongly considered when the diagnosis of serotonin toxicity is likely, especially if incomplete response has been achieved with aggressive cooling and benzodiazepine therapy.⁶² In addition, its use to treat neuromuscular rigidity and hyperthermia associated with MAOI overdose has been reported.^{10,25}

The recommended initial dose in adults is 12 mg orally, to be followed by 2 mg every 2 hours while symptoms continue.¹³ A dose of 12 to 32 mg will bind 85% to 95% of serotonin receptors.⁵⁴ The dose of cyproheptadine used to treat the serotonin toxicity may cause sedation, but this effect is a goal of therapy and should not deter clinicians from using the drug. Relative contraindications to its use include acute asthma exacerbation, GI obstruction, and age less than 2 years (due to lack of safety information for this age group).

Dantrolene

Use of dantrolene in patients with serotonin toxicity is not recommended (Antidotes in Depth: A21). Case reports citing its utility with off-label usage probably involved misdiagnosis.^{13,53} Malignant hyperthermia, for which dantrolene is actually indicated, is a disease that is completely unrelated to serotonin toxicity. In animal models of serotonin toxicity, dantrolene administration has no effect on survival.^{51,79} In addition, dantrolene has been implicated in the fatality of one case of serotonin toxicity.⁵⁶

Extracorporeal Elimination

The utility of extracorporeal measures, such as hemodialysis, to treat MAOI toxicity remains to be demonstrated. The ability to dialyze a xenobiotic depends largely on its protein binding the volume of distribution. Unfortunately, data regarding protein binding and volumes of distribution of the first-generation MAOI drugs such as isocarboxazid are not well characterized. Use of peritoneal dialysis⁶⁷ and hemodialysis⁷¹ to treat MAOI overdose has been reported in the literature. However, time to resolution of symptoms for all cases did not differ (~ 24 hours) from those in which hemodialysis was not employed. Therefore, extracorporeal elimination is not recommended in the management of MAOI overdose unless other indications are present such as severe acidemia or life-threatening hyperkalemia, or the need to eliminate dialyzable toxic coingestions.

Disposition

Recommendations for the ideal time frame for observation of patients with suspected MAOI overdose are limited by a paucity of relevant studies in the clinical toxicology literature. Patients with presumed MAOI (selective or nonselective) overdose should be observed with telemetry monitoring, preferably in an intensive care unit, for at least 24 hours regardless of the initial clinical findings. This recommendation takes into account the potential for delayed-onset of clinical toxicity as well as the potential for severe morbidity and mortality.^{70,72,96} However, patients with MAOI–food or MAOI–xenobiotic interactions may not require hospital admission if the interaction is mild, resolution of symptoms is complete, and the patient has been observed for 4 to 8 hours.

SUMMARY

- Toxicity from MAOI exposures is becoming less common due to more limited clinical usage of the traditional nonselective MAOIs; however, clinical and research use of selective MAOIs and RIMAs is increasing.
- Inhibition of MAO has effects on myriad neuronal neurotransmitters, which are responsible for the majority of the therapeutic and toxic effects of MAOIs.
- The clinical effects of MAOI overdose may be life threatening and should be managed aggressively.
- Aside from overdose, other consequential manifestations of MAOI toxicity may include hyperadrenergic crisis and the serotonin toxicity.

74 SEDATIVE-HYPNOTICS

David C. Lee

HISTORY AND EPIDEMIOLOGY

Sedative-hypnotics are xenobiotics that limit excitability (sedation) and or induce drowsiness and sleep (hypnosis). Anxiolytics (formerly known as minor tranquilizers) are medications prescribed for their sedative-hypnotic properties. Mythology of ancient cultures is replete with stories of xenobiotics that cause sleep or unconsciousness ([Chap. 1](#)). Sedative-hypnotics overdoses were described in the medical literature soon after the commercial introduction of bromide preparations in 1853. Other commercial xenobiotics that subsequently were developed include chloral hydrate, paraldehyde, sulfonyle, and urethane.

The barbiturates were introduced in 1903 and quickly supplanted the older xenobiotics. Barbiturates dominated the sedative-hypnotic market for the first half of the twentieth century. Due to their narrow therapeutic index and substantial potential for abuse, they quickly became a major health problem. By the 1950s, barbiturates were frequently implicated in overdoses and were responsible for the majority of drug-related suicides. As fatalities from barbiturates increased, attention shifted toward preventing their abuse and finding less toxic alternatives.²³ The “safer” drugs of that era included methypylon, glutethimide, ethchlorvynol, bromides, and methaqualone. Unfortunately, many of these sedative hypnotics also had significant adverse drug reactions. After the introduction of benzodiazepines in the early 1960s, barbiturates and the other alternatives were quickly replaced as commonly used sedatives in the United States.

Intentional and unintentional overdoses with sedative-hypnotics occur frequently. According to the American Association of Poison Control Centers, sedative-hypnotics is consistently one of the top five classes of xenobiotics associated with overdose fatalities ([Chap. 136](#)). With the ubiquitous worldwide use of sedative-hypnotics, they may be associated with a substantially higher number of overdoses and deaths than are officially reported.

Chlordiazepoxide, the first commercially available benzodiazepine, was initially marketed in 1960. Since then, more than 50 benzodiazepines have been marketed, and more are being developed. Compared with barbiturate overdoses, overdoses of benzodiazepines alone account for relatively few deaths.^{37,48,59} Most deaths associated with benzodiazepines result from mixed overdoses with other respiratory depressants.^{48,134}

Benzodiazepines remain the most popular prescribed anxiolytics. However, newer hypnotic pharmaceuticals zolpidem, zaleplon, zopiclone, and eszopiclone have replaced benzodiazepines as the most commonly prescribed pharmaceutical sleep aids. Melatonin and ramelteon are emerging as popular sleep aids whose effects are mediated through melatonin receptor subtypes MT₁ and MT₂ specifically.^{134,140,160} Dexmedetomidine, a central α_2 -adrenergic agonist, is now increasingly used in the hospital setting for short-term sedation.^{30,37,40,121,129,139,160,170,173,176,177,210}

This chapter focuses primarily on pharmaceuticals prescribed for their sedative-hypnotic effects, many of which interact with the γ -aminobutyric acid-A (GABA_A) receptor ([Table 74–1](#)). Specific sedative-hypnotics such as ethanol and γ -hydroxybutyric acid are discussed in more depth in their respective chapters ([Chaps. 80 and 83](#)).

TABLE 74–1. Pharmacology of Sedative-Hypnotics

	Equipotent Dosing Oral Dose (mg) ^a	<i>t</i> _{1/2} (minutes)	Protein Binding (%)	Vd (L/kg)	Active Metabolite Important
Benzodiazepines					
<i>Full agonist activity at the benzodiazepine site</i>					
Alprazolam (Xanax)	1.0	10–14	80	0.8	No

^aThese data are approximations of equipotent doses of sedatives affecting the benzodiazepine receptor and several barbiturates. All the full agonist benzodiazepines have similar anxiolytic, anxiolytic, sedative, and hypnotic effects. These effects are a reflection of dose and serum concentration. There can be significant variation of these effects according to age and sex. ^bNot presently available in the United States.

NA = not applicable; Vd = volume of distribution.

PHARMACODYNAMICS/TOXICODYNAMICS

All sedative-hypnotics induce central nervous system (CNS) depression. Most clinically effective sedative-hypnotics produce their physiologic effects by enhancing the function of GABA-mediated chloride channels via agonism at the GABA_A receptor. These receptors are the primary mediators of inhibitory neurotransmission in the brain (Chap. 14). The GABA_A receptor is a pentameric structure composed of varying polypeptide subunits associated with a chloride channel on the postsynaptic membrane. These subunits are classified into families (eg, α , β , γ). Variations in the five subunits of the GABA receptor confer the potency of its sedative, anxiolytic, hypnotic, amnestic, and muscle relaxing properties. The most common GABA_A receptor in the brain is composed of $\alpha_1\beta_2\gamma_2$ subunits. Almost all sedative-hypnotics bind to GABA_A receptors containing the α_1 subunit. One exception may be etomidate, which produces sedation at the β_2 unit and anesthesia at the β_3 subunit.^{32,99,114,131,189} Benzodiazepines will be effective only at GABA_A receptors with the γ_2 subunit. Even within classes of sedative-hypnotics, there will be varying affinities for differing subunits of the GABA receptor.^{42,99}

Many sedative-hypnotics also act at receptors other than the GABA_A receptor. Trichloroethanol and propofol, also inhibit glutamate-mediated N-methyl-D-aspartate (NMDA) receptors, thereby inhibiting excitatory neurotransmission.^{34,124,146} Certain benzodiazepines may inhibit adenosine metabolism and reuptake, thereby potentiating both A₁-adenosine (negative dromotropy) and A₂-adenosine (coronary vasodilation) receptor-mediated effects.^{110,157} Benzodiazepines can also interact with serotonergic pathways. For example, diazepam modulates morphine analgesia via interactions with serotonin receptors. In addition, the anxiolytic effects of clonazepam can be partially explained by upregulation of serotonergic receptors, specifically 5-HT₁ and 5-HT₂.^{9,111,199} Newer sleep aids, such as melatonin and ramelteon, do not appear to act at the GABA_A receptor. Instead, they are agonists at melatonin receptor subtypes MT₁ and MT₂ in the suprachiasmatic nucleus of the brain.^{15,140,160,168,175} Dexmedetomidine, a central α_2 -adrenergic agonist similar to clonidine, induces a state of “cooperative sedation.”¹⁷⁰

PHARMACOKINETICS/TOXICOKINETICS

Most sedative-hypnotics are rapidly absorbed via the gastrointestinal (GI) tract, with the rate-limiting step consisting of dissolution and dispersion of the xenobiotic. Barbiturates and benzodiazepines are primarily absorbed in the small intestine. Clinical effects are determined by their relative ability to penetrate the blood–brain barrier. Xenobiotics that are highly lipophilic penetrate most rapidly. The ultrashort-acting barbiturates are clinically active in the most vascular parts of the brain (gray matter first), with sleep occurring within 30 seconds of administration. Table 74–1 lists individual sedative-hypnotics and some of their pharmacokinetic properties.

After initial distribution, many of the sedative-hypnotics undergo a redistribution phase as they are dispersed to other body tissues, specifically fat. Xenobiotics that are redistributed, such as the lipophilic (ultrashort-acting) barbiturates and some of the benzodiazepines (diazepam, midazolam), may have a brief clinical effect as the early peak concentrations in the brain rapidly decline.

Many of the sedative-hypnotics are metabolized to pharmacologically active intermediates. This is particularly true for chloral hydrate and some of the benzodiazepines. Benzodiazepines can be demethylated, hydroxylated, or conjugated with glucuronide in the liver. Glucuronidation results in the production of inactive metabolites. Certain benzodiazepines, such as diazepam, are demethylated which produces active intermediates with a more prolonged half-life than the parent compound. Because of the individual pharmacokinetics of sedative-hypnotics and the production of active metabolites, there is often little correlation between the duration of effect and biologic half-lives.

Most sedative-hypnotics, such as the highly lipid-soluble barbiturates and the benzodiazepines, are highly protein bound. These drugs are poorly filtered by the kidneys. Elimination occurs principally by hepatic metabolism. Chloral hydrate and meprobamate are notable exceptions. Xenobiotics with a low log D (octanol-to-water partition coefficient), such as meprobamate and the longer-acting barbiturates, are poorly protein bound and more subject to renal excretion. Phenobarbital is a classic example of a drug whose elimination can be enhanced through urinary alkalization. Most other sedative-hypnotics are not amenable to urinary pH manipulation.

Overdoses of combinations of sedative-hypnotics enhance toxicity through synergistic effects. For example, both barbiturates and benzodiazepines act on the GABA_A receptor, but barbiturates prolong the opening of the chloride ionophore, whereas benzodiazepines increase the frequency of ionophore opening.¹⁶² Various sedative-hypnotics may increase the affinity of another xenobiotic at its respective binding site. For example, pentobarbital increases the affinity of γ -hydroxybutyric acid (GHB) for its non-GABA binding site.¹⁶⁴ Propofol potentiates the effect of pentobarbital on chloride influx at the GABA_A receptor.¹³³ Propofol also increases the affinity and decreases the rate of dissociation of benzodiazepines from their site on the GABA_A receptor.^{21,181} These actions increase the clinical effect of each xenobiotic and may lead to deeper central nervous system (CNS) and respiratory depression.

Another mechanism of synergistic toxicity occurs via alteration of metabolism. The combination of ethanol and chloral hydrate, historically known as a “Mickey Finn,” has additive CNS depressant effects. Chloral hydrate competes for alcohol and aldehyde dehydrogenases, thereby prolonging the half-life of ethanol. The metabolism of ethanol generates the reduced form of nicotinamide adenine dinucleotide, which is a cofactor for the metabolism of chloral hydrate to trichloroethanol, an active metabolite. Finally, ethanol inhibits the conjugation of trichloroethanol, which, in turn, inhibits the oxidation of ethanol (Fig. 74–1).^{1,17,19,56,87,101,125,142,153,154,161,200} The end result of these synergistic pharmacokinetic interactions is enhanced CNS depression.

FIGURE 74–1. Metabolism of chloral hydrate and ethanol, demonstrating the interactions between chloral hydrate and ethanol metabolism. Note the inhibitory effects (dotted lines) of ethanol on trichloroethanol metabolism and the converse.

Multiple drug–drug interactions can occur that may prolong the half-life of many sedative-hypnotics and significantly increase their potency or duration of action. The half-life of midazolam, which undergoes hepatic metabolism via cytochrome CYP3A4, can change dramatically in the presence of certain drugs that compete for its metabolism, or that induce or inhibit CYP3A4.^{118,184} For example, the half-life of midazolam rises 400-fold when coadministered with itraconazole.^{8,163} Various receptor and metabolic enzyme alterations resulting in upregulation or downregulation may occur in the setting of acute or chronic exposure to certain sedative-hypnotics.

TOLERANCE/WITHDRAWAL

Ingestions of relatively large doses of sedative-hypnotics may not have predictable effects in patients who chronically use them. This is due to tolerance, defined as the progressive diminution of effect of a particular drug with repeated

administrations that results in a need for greater doses to achieve the same effect. Tolerance occurs when adaptive neural and receptor changes (plasticity) occur after repeated exposures. These changes include a decrease in the number of receptors (downregulation), reduction of firing of receptors (receptor desensitization), structural changes in receptors (receptor shift), or reduction of coupling of sedative-hypnotics and their respective GABA_A related receptor site (Chap. 15). Tolerance can also be secondary to pharmacokinetic factors, such as enhanced elimination after repetitive doses. However, in most cases, tolerance to sedative-hypnotics is caused by pharmacodynamic changes such as receptor downregulation.¹⁶³

Cross-tolerance readily exists among the sedative-hypnotics. For example, chronic use of benzodiazepines not only decreases the activity of the benzodiazepine site on the GABA receptor but also decreases the binding affinity of the barbiturate sites.^{4,69} Many sedative-hypnotics are also associated with drug dependence after chronic exposure. Some of these, classically the barbiturates, benzodiazepines, and ethanol, are associated with life-threatening withdrawal syndromes.

CLINICAL MANIFESTATIONS

Patients with sedative-hypnotic overdoses may exhibit slurred speech, ataxia, and incoordination. Larger doses result in stupor or coma. In most instances, respiratory depression parallels CNS depression. However, not all sedative-hypnotics cause significant hypoventilation. Oral overdoses of benzodiazepines alone may lead to sedation and hypnosis, but rarely life-threatening hypoventilation. Typically, the patient may appear comatose but have relatively normal vital signs. In contrast, large intravenous doses of benzodiazepines may lead to potentially life-threatening respiratory depression. Single overdoses of zolpidem and its congeners do not typically cause life-threatening respiratory depression in adults.^{22,52,60,195}

Although the physical examination is rarely specific for a particular sedative-hypnotic, it can sometimes offer clues of exposure based on certain physical and clinical findings (Table 74–2). Hypothermia is described with most of the sedative-hypnotics but may be more pronounced with barbiturates.^{71,142} Barbiturates may cause fixed drug eruptions that often are bullous and appear over pressure-point areas. Although classically referred to as “barbiturate blisters,” this phenomenon is not specific to barbiturates as other CNS depressants including carbon monoxide, methadone, imipramine, glutethimide, and benzodiazepines can all cause bullous eruptions over pressure points. Methaqualone can cause muscular rigidity and clonus.^{2,20,26,70,143} Glutethimide can result in anticholinergic signs and symptoms.^{3,10,28} Chloral hydrate use may result in vomiting, gastritis, and cardiac dysrhythmias.^{17,19,24,56,76,87,88,116,179,188,200,212} Meprobamate overdoses may present with significant hypotension due to myocardial depression.^{27,38,67,73,81,155,216}

TABLE 74–2. Clinical Findings of Sedative-Hypnotic Overdose

<i>Clinical Signs</i>	<i>Sedative-Hypnotics</i>
Hypothermia	Barbiturates, bromides, ethchlorvynol
Unique odors	Chloral hydrate (<i>pear</i>), ethchlorvynol (<i>new vinyl shower curtain</i>)
Cardiotoxicity	
Myocardial depression	Meprobamate
Dysrhythmias	Chloral hydrate
Muscular twitching	γ-hydroxybutyric acid, methaqualone, propofol, etomidate
Acneiform rash	Bromides
Fluctuating coma	Glutethimide, meprobamate
Gastrointestinal hemorrhage	Chloral hydrate, methaqualone
Discolored urine	Propofol (green/pink)
Anticholinergic	Glutethimide

Large or prolonged intravenous doses of sedative-hypnotics may also be associated with toxicities due to their diluents. Propylene glycol is a classic example of a diluent that may accumulate with prolonged infusions of certain medications such as lorazepam. Rapid infusions of propylene glycol may induce hypotension. Accumulated amounts of propylene glycol may lead to metabolic acidosis and a hyperosmolar state with elevated serum lactate

concentrations.^{7,123,132,152,183,185,204,207,213} In one study, two-thirds of critical care patients given high doses of lorazepam (0.16 mg/kg/h) for more than 48 hours had significant accumulations of propylene glycol as manifested by hyperosmolality and an anion gap metabolic acidosis⁷ (Chap. 55).

DIAGNOSTIC TESTING

When overdose is a primary concern in the undifferentiated comatose patient without a clear history, laboratory testing may be useful to exclude metabolic abnormalities. This may include electrolytes, liver enzymes, thyroid function tests, blood urea nitrogen, creatinine, glucose, venous or arterial blood gas analysis, and cerebrospinal fluid analysis. With any suspected intentional overdose, a serum acetaminophen concentration should be obtained. Diagnostic imaging studies, such as computed tomography scans of the head, may be warranted on a case by case basis.

Routine laboratory screening for “drugs of abuse” generally is not helpful in the management of undifferentiated comatose adult patients. However, screening may be useful for epidemiologic purposes in a particular community. These tests vary in type, sensitivity, and specificity. Furthermore, many sedative-hypnotics are not included on standard screening tests for drugs of abuse. For example, a typical benzodiazepine urine screen identifies metabolites of 1,4-benzodiazepines, such as oxazepam or desmethyldiazepam. Many benzodiazepines that are metabolized to alternative compounds remain undetected and thus may exhibit a false-negative result on the benzodiazepine-screening assay. Benzodiazepines that are 7-amino analogs, such as clonazepam and flunitrazepam, may not be detected because they do not have a metabolite with a 1,4-benzodiazepine structure. Alprazolam and triazolam are not detected because they undergo minimal metabolism.⁴⁵

Specific concentrations of xenobiotics such as ethanol or phenobarbital may be helpful to confirm or disprove exposure. However, specific concentrations of most other sedative-hypnotics are not routinely performed in hospital laboratories. Abdominal radiographs may detect chloral hydrate in the gastrointestinal tract because of its potential radiopacity (Chap. 5). Although immediate identification of a particular sedative-hypnotic may be helpful in predicting the length of toxicity, it rarely affects the acute management of the patient. One exception is phenobarbital, for which urinary alkalization and multiple-dose activated charcoal (MDAC) may enhance elimination.^{50,92,128,141}

MANAGEMENT

Death secondary to sedative-hypnotic overdose usually results from cardiorespiratory collapse. Careful attention should focus on monitoring and maintaining adequate airway, oxygenation, and hemodynamic support. Supplemental oxygen, respiratory support, and prevention of aspiration are the cornerstones of treatment. Hemodynamic instability should be treated initially with volume expansion. With proper supportive care and adequate airway and or respiratory support as needed, patients with sedative-hypnotic overdoses should eventually recover. Patients with meprobamate and chloral hydrate overdoses may present with both respiratory depression and cardiac toxicity. Meprobamate toxicity may be associated with myocardial depression and significant hypotension, often resistant to standard intravenous fluid resuscitation.²⁷ The cardiotoxic effects of chloral hydrate include lethal ventricular dysrhythmias, resulting from its active halogenated metabolite trichloroethanol. In the setting of cardiac dysrhythmias from chloral hydrate, judicious use of β -adrenergic antagonists is recommended.^{17,19,200,212}

The use of gastrointestinal decontamination should be decided on a case by case basis. The benefits of activated charcoal (AC) must be balanced with the risks of its aspiration and subsequent potential for pulmonary toxicity. The use of AC should be determined judiciously based on the current mental status of the patient, the potential for further deterioration, the xenobiotic(s) ingested, and the expected clinical course. Phenobarbital overdose is one particular scenario in which MDAC may be considered. MDAC increases phenobarbital elimination by 50% to 80%.^{11,12,16} However, in the only controlled study in intubated, phenobarbital-poisoned patients who were randomized to single-dose activated charcoal versus MDAC, no statistical difference was demonstrated in outcome measures (time to extubation and length of hospitalization).¹²⁷ AC may have potential benefits in certain situations after ensuring adequate airway protection (Antidotes in Depth: A1).

Although the efficacy of delayed orogastric lavage is controversial, orogastric lavage may be considered in overdoses with xenobiotics that slow GI motility or that are known to develop concretions, specifically phenobarbital and meprobamate.^{27,75,150} Orogastric lavage in the setting of oral benzodiazepine overdoses alone is not recommended, as the benefits of lavage are minimal compared to the significant risks of aspiration (Chap. 8). No antidote counteracts all sedative-hypnotic overdoses. Flumazenil, a competitive benzodiazepine antagonist, rapidly reverses the sedative effects of benzodiazepines as well as zolpidem and its congeners.^{90,148,166,198,202,209} However, flumazenil can precipitate life-threatening benzodiazepine withdrawal in benzodiazepine-dependent patients. Flumazenil use is also associated with seizures, especially in patients who have overdosed on tricyclic antidepressants^{72,109,166,167,194,209} (Antidotes in Depth: A22).

Because the lethality of sedative-hypnotics is associated with their ability to cause respiratory depression,

asymptomatic patients can be downgraded to a lower level of care after a period of observation with no signs of respiratory depression. Patients with symptomatic overdoses of long-acting sedative hypnotics, such as meprobamate and clonazepam, or drugs that can have significant enterohepatic circulation, such as glutethimide, may require 24 hours of observation in the intensive care unit ([Chap. 11](#)). Patients with mixed overdoses of various sedative-hypnotics and CNS depressants also warrant closer observation for respiratory depression due to synergistic respiratory depressant effects.

SPECIFIC SEDATIVE-HYPNOTICS

Barbiturates

Barbital became the first commercially available barbiturate in 1903. Although many other barbiturates were subsequently developed, their popularity has greatly waned since the introduction of benzodiazepines. Barbiturates are derivatives of barbituric acid (2,4,6-trioxo-hexa-hydropyrimidine), which itself has no CNS depressant properties. The addition of various side chains influences the pharmacologic properties. Barbiturates with long side chains tend to have increased lipophilicity, potency, and slower rates of elimination. However, the observed clinical effects also depend on absorption, redistribution, and the presence of active metabolites. For this reason, the duration of action of barbiturates (like those of benzodiazepines) may not correlate well with their biologic half-lives.

Oral barbiturates are preferentially absorbed in the small intestine and are eliminated by both hepatic and renal mechanisms. Longer-acting barbiturates tend to be more lipid soluble, more protein bound, have a higher pK_a , and are metabolized almost completely by the liver. Renal excretion of unchanged drug is significant for phenobarbital, a long-acting barbiturate with a relatively low pK_a (7.24). Alkalinizing the urine with sodium bicarbonate to a urinary pH of 7.5 to 8.0 can increase the amount of phenobarbital excreted by 5- to 10-fold. This procedure is not effective for the short-acting barbiturates because they have higher pK_a values, are more protein bound, and are primarily metabolized by the liver with very little unchanged drug excreted by the kidneys (*Antidotes in Depth: A5* and [Chap. 10](#)). Although several authors have questioned the clinical benefit of urinary alkalinization,¹⁴¹ this practice is still recommended to enhance renal elimination of phenobarbital.

Barbiturates (especially the shorter-acting barbiturates) can accelerate their own hepatic metabolism by cytochrome P450 enzyme autoinduction. Phenobarbital is a nonselective inducer of hepatic cytochromes, the greatest effects being on CYP2B1, CYP2B2, and CYP2B10, although CYP3A4 is also affected.^{82,117,145,159,182} Not surprisingly, a variety of interactions are reported following the use of barbiturates. Clinically significant interactions as a result of enzyme induction lead to increased metabolism of β -adrenergic antagonists, corticosteroids, doxycycline, estrogens, phenothiazines, quinidine, theophylline, and many other xenobiotics.

Similar to other sedative-hypnotics, patients with significant barbiturate overdoses present with CNS and respiratory depression. Hypothermia and cutaneous bullous lesions are often present. These two signs are also described for other patients with sedative-hypnotic overdoses, but they may be more pronounced with barbiturates.^{14,44} Early deaths caused by barbiturate ingestions result from respiratory arrest and cardiovascular collapse. Delayed deaths result from acute kidney failure, pneumonia, acute respiratory distress syndrome, cerebral edema, and multiorgan system failure as a result of prolonged cardiorespiratory depression.^{3,58}

Benzodiazepines

The commercial use of benzodiazepines began with the introduction of chlordiazepoxide for anxiety in 1961 and diazepam for seizures in 1963. Benzodiazepines are used principally as sedatives and anxiolytics. Clonazepam is the only benzodiazepine approved for use as a chronic anticonvulsant. Benzodiazepines may rarely cause paradoxical psychological effects, including nightmares, delirium, psychosis, and transient global amnesia.^{84,103,106,203,206,215} The incidence and intensity of CNS adverse events increases with age.¹⁰²

Similar to barbiturates, variations of the benzodiazepine side chains influence potency, duration of action, metabolites, and rate of elimination. Most benzodiazepines are highly protein bound and lipophilic. They passively diffuse into the CNS, their main site of action. Because of their lipophilicity, benzodiazepines are extensively metabolized via oxidation and conjugation in the liver prior to their renal elimination.

Benzodiazepines bind nonselectively to “central” benzodiazepine sites located throughout the brain. These sites contain the GABA_A α and γ subunits.^{42,193} The binding of the benzodiazepine to its particular site changes the GABA receptor to “lock” into a position that promotes GABA binding to the GABA receptor. Benzodiazepines that are active at the α_1 subunit are hypothesized to affect anxiety, sleep, and amnesia, whereas those that are active in the α_2 and α_3 subunits tend to have greater anxiolytic properties. “Peripheral” benzodiazepine sites are found throughout the body, with the greatest concentrations in steroid-producing cells in the adrenal gland, anterior pituitary gland, and reproductive organs. These sites are not affiliated with the GABA receptor (Antidotes in Depth: A23).

One unique property of the benzodiazepines is their relative safety even after substantial ingestion, which probably results from their GABA receptor properties.^{42,119} Unlike many other sedative-hypnotics, benzodiazepines do not open GABA channels independently at high concentrations. Benzodiazepines are not known to cause any specific systemic injury, and their long-term use is not associated with specific organ toxicity. Deaths resulting from isolated benzodiazepine ingestions alone are extremely rare. Most often deaths are secondary to a combination of alcohol or other sedative-hypnotics.^{156,203,206} Supportive care is the mainstay of treatment.

Tolerance to the sedative effects of benzodiazepines occurs more rapidly than does tolerance to the antianxiety effects.^{93,137} Abrupt discontinuation following long-term use of benzodiazepines may precipitate benzodiazepine withdrawal. This is characterized by autonomic instability, changes in perception, paresthesias, headaches, tremors, and seizures. Withdrawal from benzodiazepines is common, manifested by almost one-third of long-term users.⁸⁴ Alprazolam and lorazepam are associated with more severe withdrawal syndromes compared with chlordiazepoxide and diazepam.^{84,85} This is likely due to the fact that both chlordiazepoxide and diazepam have active metabolites. Withdrawal may also occur when a chronic user of a particular benzodiazepine is switched to another benzodiazepine with different receptor activity.⁹⁶

Chloral Hydrate

First introduced in 1832, chloral hydrate belongs to one of the oldest classes of pharmaceutical hypnotics, the chloral derivatives. Although still used sporadically in children, its use has substantially decreased.^{1,95,125} Chloral hydrate is well absorbed but is irritating to the GI tract. It has a wide tissue distribution, rapid onset of action, and rapid hepatic metabolism by alcohol and aldehyde dehydrogenases. Trichloroethanol is a lipid soluble, active metabolite that is responsible for the hypnotic effects of chloral hydrate. It has a serum half-life of 4 to 12 hours and is metabolized to inactive trichloroacetic acid by alcohol dehydrogenases. It is also conjugated with glucuronide and excreted by the kidney as urochloralic acid. Less than 10% of trichloroethanol is excreted unchanged.

Metabolic rates in children vary widely because of variable development and function of hepatic enzymes, in particular glucuronidation.^{18,101} The elimination half-life of chloral hydrate and trichloroethanol is markedly increased in children

younger than 2 years. This may be especially of concern in neonates and in infants exposed to repetitive doses.

Acute chloral hydrate poisoning is unique compared with that of other sedative-hypnotics. Cardiac dysrhythmias are believed to be the major cause of death.⁵⁷ Chloral hydrate and its metabolites reduce myocardial contractility, shorten the refractory period, and increase myocardial sensitivity to catecholamines. Persistent cardiac dysrhythmias (ventricular fibrillation, ventricular tachycardia, torsade de pointes) are common terminal events.¹⁰⁰ Standard antidysrhythmics often are ineffective, and β -adrenergic antagonists are considered the treatment of choice.^{17,19,24,94,179,200,212} In addition to cardiotoxicity, chloral hydrate toxicity may cause vomiting, hemorrhagic gastritis, and rarely gastric and intestinal necrosis, leading to perforation and esophagitis with stricture formation.^{88,188} Chloral hydrate is radiopaque and may be detected on radiographs; however, a negative radiograph should not be used to exclude chloral hydrate ingestion. Few hospital-based laboratories have the ability to rapidly detect chloral hydrate or its metabolites.

Meprobamate/Carisoprodol

Meprobamate was introduced in 1950 and was used for its muscle-relaxant and anxiolytic characteristics. Carisoprodol, which was introduced in 1955, is metabolized to meprobamate. Both drugs have pharmacologic effects on the GABA_A receptor similar to those of the barbiturates. Like barbiturates, meprobamate can directly open the GABA-mediated chloride channel and may inhibit NMDA receptor currents.¹³⁵ Both are rapidly absorbed from the GI tract. Meprobamate is metabolized in the liver to inactive hydroxyl and glucuronide metabolites that are excreted almost exclusively by the kidney. Of all the nonbarbiturate tranquilizers, meprobamate is most likely to produce euphoria.^{73,74} Unlike most sedative-hypnotics, meprobamate causes profound hypotension from direct myocardial depression.²⁷ Adherent masses or bezoars of pills have been discovered in the stomach at autopsy after large meprobamate ingestions.¹⁵⁰ Orogastric lavage with a large-bore tube and MDAC may be indicated for patients with significant meprobamate ingestion. However, the potential benefits of orogastric lavage must be weighed against the risks of aspiration. Whole-bowel irrigation may be helpful if multiple pills or small concretions are suspected. Patients can experience recurrent toxic manifestations as a result of concretion formation with delayed drug release and absorption. Careful monitoring of the clinical course is essential even after the patient shows initial improvement because recurrent and cyclical CNS depression can occur.¹⁵⁰

Bromides

Bromides were used in the past as “nerve tonics,” headache remedies, and anticonvulsants. Although medicinal bromides have largely disappeared from the US pharmaceutical market, bromide toxicity still occurs through the availability of bromide salts of common drugs, such as dextromethorphan.¹¹² Poisoning also may occur in immigrants and travelers from other countries where bromides are still therapeutically used.⁴⁹ An epidemic of more than 400 cases of mass bromide poisoning occurred in the Cacuo municipality of Luanda Province, Angola, in 2007. According to a World Health Organization report, the etiology of the bromide exposure in these cases was believed to be table salt contaminated with sodium bromide. Although the majority of persons affected were children, no actual deaths were attributed to bromide poisoning in this epidemic.²⁰¹

Bromides tend to have long half-lives, and toxicity typically occurs overtime as concentrations accumulate in tissue. Bromide and chloride ions have a similar distribution pattern in the extracellular fluid. It is postulated that because the bromide ion moves across membranes slightly more rapidly than the chloride ion, it is more quickly reabsorbed in the tubules from the glomerular filtrate than the chloride ion. Although osmolar equilibrium persists, CNS function is progressively impaired by a poorly understood mechanism, with resulting inappropriateness of behavior, headache, apathy, irritability, confusion, muscle weakness, anorexia, weight loss, thickened speech, psychotic behavior, tremulousness, ataxia, and, eventually, coma. Delusions and hallucinations can occur. Bromide can lead to hypertension, increased intracranial pressure, and papilledema.^{6,25,49,68,174,180,214} Chronic use of bromides also produces dermatologic changes called bromoderma, with the hallmark characteristic of a facial acneiform rash.^{64,180} Toxicity with bromides during pregnancy may lead to accumulation of bromide in the fetus.¹²⁶ A spurious laboratory result of hyperchloremia with decreased anion gap may result from the interference of bromide with the chloride assay on older analyzers²⁰⁸ (Chap. 19). Thus, an isolated elevated serum chloride concentration with neurologic symptoms should raise suspicion of possible bromide poisoning.

Zolpidem/Zaleplon/Zopiclone/Eszopiclone

These oral xenobiotics have supplanted benzodiazepines as the most commonly prescribed sleep aid medications.⁴⁶ Although they are structurally unrelated to the benzodiazepines, they bind preferentially to the benzodiazepine site subtype in the brain that contains the GABA_A α_1 subunit.⁴² They have a lower affinity for benzodiazepine sites that contain the other α isoforms, therefore they have potent hypnotic effects with less potential for dependence and anticonvulsant properties.⁶³ Each of these xenobiotics has a relatively short half-life (≤ 6 hours), with zaleplon exhibiting the shortest half-life (1 hour). Unlike benzodiazepines that prolong the first two stages of sleep and shorten stages 3 and 4 of rapid eye movement sleep, zolpidem and its congeners all decrease sleep latency with little effect on sleep architecture. Because of their receptor selectivity, they appear to have minimal effect at other sites on the GABA_A receptor that mediate anxiolytic, anticonvulsant, or muscle-relaxant effects.^{86,190}

They are hepatically metabolized by various CYP450 enzymes. Zolpidem is mainly metabolized by CYP3A4. Zaleplon is primarily metabolized by aldehyde oxidase, but CYP3A4 is also involved in parent compound oxidation. Zopiclone is primarily metabolized by CYP3A4 and CYP2C8, whereas eszopiclone is metabolized mainly by CYP3A4 and CYP2E1. Various pharmacokinetic interactions with inhibitors or inducers of CYP450 enzymes and these medications are reported.⁶²

In isolated overdoses, drowsiness and CNS depression are common. However, prolonged coma with respiratory depression is exceptionally rare. Isolated overdoses usually manifest with depressed level of consciousness without respiratory depression. For example, even at 40 times the therapeutic dose of zolpidem, no biologic or electrocardiographic abnormalities were reported.⁵² Zopiclone overdoses are rarely associated with methemoglobinemia.⁵¹ Tolerance to zolpidem and its congeners occurs, and as expected, withdrawal follows abrupt discontinuation of chronic use. The withdrawal syndrome is typically mild.^{61,197} Flumazenil may reverse the hypnotic or cognitive effects of these xenobiotics (Antidotes in Depth: A22).^{90,209} Due to increasing prevalence of these xenobiotics, they have been associated with increasing hospitalizations especially when ingested with other sedative hypnotics.²¹⁸ Deaths have resulted when zolpidem was taken in large amounts with other CNS depressants.⁵²

Propofol

Propofol is a rapidly acting intravenous sedative-hypnotic that is both a postsynaptic GABA_A agonist and induces presynaptic release of GABA.^{115,181} Propofol is also an antagonist at NMDA receptors.^{80,165,217} In addition, propofol interacts with dopamine, promotes nigral dopamine release possibly via GABA_B receptors,^{120,151} and has partial agonist properties at dopamine (D₂) receptors.¹⁴⁹ Propofol is used for procedural sedation and either induction or maintenance of general anesthesia. It is highly lipid soluble, so it crosses the blood-brain barrier rapidly. The onset of anesthesia usually occurs in less than one minute. The duration of action after short-term dosing is usually less than 8 minutes due to its rapid redistribution from the CNS.

Propofol use is associated with various adverse events. Acutely, propofol causes dose-related respiratory depression. Propofol may decrease systemic arterial pressure and cause myocardial depression. Although short-term use of propofol does not typically cause dysrhythmias or myocardial ischemia, atropine-sensitive bradycardias are noted, specifically

sinus bradycardia and Mobitz type 1 atrioventricular block.^{178,196,211} Short-term use of propofol in the perioperative setting is associated with a myoclonic syndrome manifesting as opisthotonus, myoclonus, and sometimes myoclonic seizurelike activity.^{104,113}

Prolonged propofol infusions, typically more than 48 hours at rates of 4 to 5 mg/kg/h or greater, are associated with a life-threatening propofol-infusion syndrome involving metabolic acidosis, cardiac dysrhythmias, and skeletal muscle injury.^{77,78} The clinical signs of propofol infusion syndrome often begin with the development of a new right bundle branch block and ST segment convex elevations in the electrocardiogram precordial leads.⁷⁷ Predisposing factors to the development include young age, severe brain injury (especially in the setting of trauma), respiratory compromise, concurrent exogenous administration of catecholamines or glucocorticoids, inadequate carbohydrate intake, and undiagnosed mitochondrial myopathy. Some authors propose a “priming” and “triggering” mechanism for propofol infusion syndrome with endogenous glucocorticoids, catecholamines, and possibly cytokines as “priming” agents, and exogenous catecholamines and glucocorticoids in the setting of high-dose propofol infusion as “triggering” stimuli.¹⁸⁶ Propofol is suggested to induce disruption of mitochondrial free fatty acid utilization and metabolism, causing a syndrome of energy imbalance and myonecrosis similar to mitochondrial myopathies.^{29,158,187} Case reports associate propofol with metabolic acidosis, elevated lactate concentration, and fatal myocardial failure in both children and young adults. However, this syndrome is also reported in older adults.¹²² Cases of metabolic acidosis may be associated with an inborn disorder of acylcarnitine metabolism.²⁰⁵ Prolonged propofol infusions may unmask previously undiagnosed myopathy that would cause them to be at increased risk for propofol infusion syndrome, especially in children. Despite the increasing number of reports of propofol infusion syndrome in the literature, a direct cause and effect relationship remains to be fully elucidated.

The unique nature of the carrier base of propofol, a milky soybean emulsion formulation, is associated with multiple adverse drug events. It is a fertile medium for many organisms, such as enterococcal, pseudomonal, staphylococcal, streptococcal, and candidal strains. In 1990, the US Centers for Disease Control and Prevention reported an outbreak of *Staphylococcus aureus* associated with contaminated propofol. This carrier base also impairs macrophage function,²⁹ causes hypertriglyceridemia^{41,83,91,158,187} and histamine-mediated anaphylactoid reactions,^{43,79,187} and impairs platelet and coagulation function.^{5,39}

Etomidate

Etomidate is an intravenous nonbarbiturate, hypnotic primarily used as an anesthesia induction agent. It is active at the GABA_A receptor, specifically the β_2 and β_3 subunits.^{32,114} Only the intravenous formulation is available in the United States. The onset of action is less than 1 minute and its duration of action is less than 5 minutes.

Etomidate is commercially available as a 2 mg/mL solution in a 35% propylene glycol solution. Propylene glycol toxicity from prolonged etomidate infusions is implicated in the development of hyperosmolar metabolic acidosis (Chap. 55).^{89,98,183,185} Etomidate has minimal effect on cardiac function, but rare cases of hypotension are reported.^{53-55,169} Etomidate has both proconvulsant and anticonvulsant properties.^{33,130} Involuntary muscle movements are common during induction and may be caused by etomidate interaction with glycine receptors at the spinal cord level.^{36,107,108}

Etomidate depresses adrenal production of cortisol and aldosterone; therefore, it is associated with adrenocortical suppression, usually after prolonged infusions.^{147,191,192} Etomidate has been associated with increased morbidity and mortality in critically ill and trauma patients.^{35,65} However, other authors question the clinical significance of adrenal suppression from etomidate administration and dispute its association with adverse outcomes.^{66,171,172} In the appropriate setting, etomidate does not appear to have any greater risk of significant adverse events compared with its counterparts.

Dexmedetomidine

Dexmedetomidine is a central α_2 -adrenergic agonist that decreases central presynaptic catecholamine release, primarily in the locus coeruleus. It has a terminal half-life of 1.8 hours and its volume of distribution is less than 1 L/kg. When dexmedetomidine is used to help wean patients from ventilators, sedation is achieved with less associated delirium as compared with other agents.^{121,170} It is also used for procedural sedation in certain settings such as interventional radiology

procedures and awake fiberoptic intubations. When compared with propofol, dexmedetomidine sedation may lessen opioid requirements in postoperative patients. Dexmedetomidine has been used as an adjunctive agent in benzodiazepine, opioid, or ethanol withdrawal.^{37,40,47,138,144,176,177}

Dexmedetomidine has minimal effect at the GABA_A receptor. Unlike other sedative-hypnotics, it is not associated with significant respiratory depression. Although mechanistically similar to clonidine, dexmedetomidine does not appear to cause as much respiratory depression as clonidine. Dexmedetomidine is said to induce a state of “cooperative sedation,” in which a patient is sedated but yet able to interact with health care providers. Dexmedetomidine may also have analgesic effects.³¹

Dexmedetomidine is currently only approved for use for less than 24 hours. Extensive safety trials have not yet explored its use beyond 24 hours. Unlike clonidine, rebound hypertension and tachycardia have not been described upon cessation. Because dexmedetomidine decreases central sympathetic outflow, its use should probably be avoided in patients whose clinical stability is dependent on high resting sympathetic tone. The most common adverse effects from its use are nausea, dry mouth, bradycardia, and varying effects on blood pressure (usually hypertension followed by hypotension). Slowing of the continuous infusion may help to prevent or lessen the hypotensive effects.³¹ In one case, a 60-fold overdose in a child was associated with hypoglycemia.¹³

Ramelteon and Melatonin

Ramelteon is a synthetic melatonin-analog that is FDA approved for the treatment of chronic insomnia. Ramelteon is thought to decrease both latency to sleep induction and length of persistent sleep.¹⁶⁰ Melatonin (N-acetyl-5-methoxytryptamine) and melatonin-containing products are sold as dietary supplements. Melatonin is naturally synthesized from tryptophan by the enzyme 5-hydroxyindole-O-methyltransferase, primarily within the pineal gland in humans. Melatonin and ramelteon both act as agonists at MT₁ and MT₂ receptors, which are G protein–coupled receptors mainly located in the suprachiasmatic nucleus of the brain.¹²⁷ Ramelteon is specific for MT₁ and MT₂ receptors, whereas melatonin is active at other melatonin receptors not likely involved in sleep. MT₁ receptors appear to be involved in sleep induction, whereas MT₂ receptors are involved in regulation of the circadian sleep-wake cycle in humans.¹⁶⁸

Ramelteon is administered as an oral medication that is rapidly absorbed but undergoes significant first-pass metabolism. Ramelteon is metabolized primarily by CYP1A2. The half-life of ramelteon with therapeutic use is roughly 1.5 hours.

Adverse effects of ramelteon are often mild and usually include dizziness, fatigue, and headache. The endocrine effects of long-term exposure to ramelteon seem to be limited to subclinical increases in serum prolactin concentration in women and do not appear to affect adrenal or thyroid function.¹³⁶ In addition, ramelteon has a low abuse potential and does not appear to be associated with a withdrawal syndrome or with rebound insomnia.^{60,97,105} As of yet, there are no reported cases of significant toxicity from ramelteon overdose.

SUMMARY

- Treatment is largely conservative with little need for GI decontamination.
- Sedative-hypnotics encompass a wide range of xenobiotics that predominantly interact with the GABA_A receptor but can also have varying mechanisms of action.
- Patients with sedative-hypnotic overdoses often present with the primary manifestation of CNS depression; however, death typically results from respiratory depression and subsequent cardiovascular collapse in the setting of concurrent coingestion of other CNS depressants.
- Careful monitoring, airway protection, and proper supportive care are the cornerstones of treatment. Specific antidotes such as flumazenil and treatments such as hemodialysis are rarely indicated.

A22 ANTIDOTES IN DEPTH

Flumazenil

Mary Ann Howland

INTRODUCTION

Flumazenil is a competitive benzodiazepine receptor antagonist. Its role in patients with an unknown overdose is limited because seizures and dysrhythmias may develop when the effects of a benzodiazepine are reversed if the patient has taken a mixed overdose. Flumazenil also has the potential to induce benzodiazepine withdrawal symptoms, including seizures in patients who are benzodiazepine dependent. Flumazenil does not reliably reverse the respiratory depression induced by intravenous (IV) benzodiazepines.²¹ Flumazenil is the ideal antidote for the relatively few patients who are both naïve to benzodiazepines and who overdose solely on a benzodiazepine as well as benzodiazepine-naïve patients whose benzodiazepine component must be reversed after procedural sedation. Because the duration of effect of flumazenil is shorter than that of most benzodiazepines, repeat doses may be necessary and vigilance is warranted. Flumazenil has no role in the management of ethanol intoxication. Flumazenil may be considered for patients with hepatic encephalopathy although further study is necessary before it can be recommended.⁴ Case reports raise the possibility of a role for flumazenil in patients with paradoxical reactions to therapeutic doses of benzodiazepines.⁷¹ Flumazenil was not effective in overdose of baclofen in which a benzodiazepine receptor is not involved.¹⁵ Flumazenil is effective for overdoses of zolpidem and zaleplon, nonbenzodiazepines that interact with β_1 receptors, a subclass of central benzodiazepine receptors.^{43,53,56}

HISTORY

The initial work of Haefely and Hunkeler⁶⁷ on chlordiazepoxide synthesis led to an attempt to develop benzodiazepine derivatives that would act as antagonists.³³ This endeavor was initially unsuccessful but led to the promising γ -aminobutyric acid (GABA) hypothesis as the benzodiazepine mechanism of action. In 1977 radioligand binding identified

specific high-affinity benzodiazepine binding sites. Other investigators simultaneously isolated a product produced by a *Streptomyces* species that had the basic 1,4-benzodiazepine structure. Synthetic derivatives of this molecule led to the creation of benzodiazepines with potent anxiolytic and anticonvulsant activity and diminished sedative and muscle-relaxing properties. Testing revealed these derivatives had high in vitro binding affinities, but lacked in vivo activity. An inability to enter the central nervous system (CNS) was considered an explanation for the discordance. During an experiment that attempted to demonstrate CNS penetration of these derivatives, diazepam given to incapacitate the animals had a surprisingly weak effect. This lack of potency led to the discovery of a benzodiazepine antagonist. Further modifications led to the synthesis of flumazenil (Ro 15-1788).^{20,57}

PHARMACOLOGY

Mechanism of Action

The benzodiazepine receptor modulates the effect of GABA on the GABA_A receptor by increasing the frequency of Cl⁻ channel opening, leading to hyperpolarization. Agonists such as diazepam stimulate the benzodiazepine receptor to produce anxiolytic, anticonvulsant, sedative-hypnotic, amnestic, and muscle relaxant effects. Flumazenil is a water-soluble benzodiazepine analog with a molecular weight of 303 Da. It is a competitive antagonist at the benzodiazepine receptor, with very weak agonist properties both in animal models and in humans.⁵² Inverse agonists bind the benzodiazepine receptor and result in the opposite effects of anxiety, agitation, and seizures. Antagonists, such as flumazenil, competitively occupy the benzodiazepine receptor without causing any functional change and without allowing an agonist or inverse agonist access to the receptor. The zero set point of intrinsic activity may be influenced by the activity of the GABA system or by chronic treatment with benzodiazepines.²⁴ Positron emission tomography investigations reveal that 1.5 mg of flumazenil leads to an initial receptor occupancy of 55%, whereas 15 mg causes almost total blockade of benzodiazepine receptor sites.⁶⁰

PHARMACOKINETICS AND PHARMACODYNAMICS

Table A22–1 summarizes the physicochemical and pharmacologic properties of flumazenil.^{21,37} Volunteer studies demonstrate that the ability of flumazenil to reverse the effects of sedating doses of IV benzodiazepines (eg, 30 mg diazepam, 3 mg lorazepam, 10 mg midazolam) is dose dependent and begins within minutes.¹⁸ Peak effects occur within 6 to 10 minutes.²¹ Most individuals achieve complete reversal of benzodiazepine effect with a total IV dose of 1 mg, titrated in 0.2 mg aliquots.^{5,14} A 3 mg IV dose produces similar effects that last approximately twice as long as the 1 mg dose.

TABLE A22–1. Physicochemical and Pharmacologic Properties of Flumazenil

pK _a	Weak base
LogD	1.15 (octanol/aqueous PO ₄ buffer)
Volume of distribution	1.06 L/kg
Distribution half-life (t _{1/2α})	≤5 minutes
Metabolism	Hepatic: three inactive metabolites High clearance
Elimination	First order
Protein binding	54%–64%
Elimination half-life (t _{1/2β})	53 minutes
Onset of action	1–2 minutes
Duration of action	Dependent on dose and elimination of benzodiazepine, time interval, dose of flumazenil, and hepatic function

ROLE IN CONSCIOUS SEDATION

A number of studies evaluated patients who received midazolam or diazepam (average doses of 10 and 30 mg,

respectively) as conscious sedation for endoscopy or cardioversion.^{6,13,14,17,39,40} When a benzodiazepine is given for conscious sedation during a procedure, flumazenil appears safe and effective for reversal of sedation and partial reversal of amnesia and cognitive impairment.²⁷ Most patients respond to total doses of 0.4 to 1 mg.²¹ Administering flumazenil slowly at a rate of 0.1 mg/min minimizes the disconcerting symptoms associated with rapid arousal, such as confusion, agitation, and emotional lability. Residual sedation becomes evident within 20 to 120 minutes, depending on the dose and pharmacokinetics of the specific agonist benzodiazepine and the dose of flumazenil.²⁷ For this reason, patients must be carefully monitored and subsequent doses of flumazenil titrated to clinical response. Because the amnestic effect of benzodiazepines and the cognitive and psychomotor effects are not fully reversed, posttreatment instructions should be reinforced in writing and given to a responsible caregiver accompanying the patient.^{18,27} Because of the risk of resedation, health care professionals infrequently elect to use flumazenil.

Two patients undergoing endoscopy who developed seizures following benzodiazepine reversal are reported.⁶⁴ One patient had a history of seizures, and the other had no obvious etiology. Both patients recovered uneventfully.

ROLE IN PARADOXICAL REACTIONS

Paradoxical reactions to benzodiazepines are unpredictable and documented in as many as 1% to 10% of adults and in 3.4% of children.^{30,48,49} Common features include worsening restlessness, agitation, disorientation, flailing, and dysphoria.^{26,28,54,71} The mechanism is unclear and has been attributed to a disinhibition reaction.²³ These reactions are reported to occur from several minutes to 210 minutes after initiation of sedation.^{28,71} Management strategies include administering higher doses of the benzodiazepines, adding other drugs such as opioids or droperidol, stopping the procedure, and using flumazenil.^{26,49,54,71} IV flumazenil was administered to six adults with paradoxical reactions to midazolam in 0.1 mg aliquots. Doses of 0.2 to 0.5 mg were effective in all the patients with a response occurring within 30 seconds.⁷¹ Attention to other causes of unexpected behavior such as hypoxia or hypoglycemia must be addressed and corrected.

ROLE IN THE OVERDOSE SETTING

Although the flumazenil package insert carries an indication for the management of benzodiazepine overdose, the role of flumazenil in the overdose setting is controversial.^{41,68} The first argument against flumazenil use is the rare morbidity and mortality associated with benzodiazepine use. An analysis of 702 patients who had taken benzodiazepines alone or in combination with ethanol or other drugs and were subsequently admitted to a medical intensive care unit over a 14-year period revealed a 0.7% fatality rate (five deaths) and 9.8% complication rate (69 patients).³⁶ In comparison, the fatality rate for patients with nonbenzodiazepine related overdoses was 1.6% (55 of 3430 patients). In the pure benzodiazepine group, two patients died and 18 (12.5%) of 144 patients had complications, mostly aspiration pneumonitis and decubitus ulcers. Proponents of flumazenil therapy suggest that some of the 29 diagnostic procedures used in the patients were unnecessary, and some of the complications could have been prevented by the use of flumazenil. Others suggest that many of the cases of aspiration pneumonitis occurred prior to hospital admission and that the patients also suffered from trauma and infectious diseases, making most diagnostic procedures necessary.

In an effort to develop indications for safe and effective use of flumazenil, overdosed comatose patients were retrospectively assigned to either a low-risk or non-low-risk group.³¹ Low-risk patients had CNS depression with normal vital signs, no other neurologic findings, no evidence of ingestion of a tricyclic antidepressant by history or electrocardiography, no seizure history, and absence of an available history of chronic benzodiazepine use. All other patients fell into the non-low-risk category. Of 35 consecutive comatose patients, 4 were assigned to the low-risk group. Flumazenil resulted in complete awakening in three patients and partial awakening in the fourth patient in the low-risk group, with no adverse events. In the non-low-risk group of 31 patients, flumazenil caused complete awakening in four patients and partial awakening in five patients. Seizures occurred in five patients, of whom only one had a history of seizures, five were long-term benzodiazepine users, four had abnormal vital signs prior to reversal, and three had evidence of hyperreflexia or myoclonus. Therefore, although flumazenil use probably was safe and effective in the low-risk group, few patients could be considered low risk. The risk of seizures appears substantial in non-low-risk patients.

The risks of flumazenil usually outweigh the benefits in patients with overdoses.⁶¹ When non-benzodiazepine-dependent patients ingest benzodiazepines alone in overdose, as rarely occurs in adults but might be expected in children, the risks associated with flumazenil are limited.^{41,73} Table A22–2 summarizes the indications for flumazenil use in the overdose setting.

TABLE A22–2. Indications for Flumazenil Use in the Overdose Setting

Pure benzodiazepine overdose in a nontolerant individual who has

- Central nervous system depression
- Normal vital signs, including SaO₂
- Normal electrocardiogram
- Otherwise normal neurologic examination

ROLE IN NONBENZODIAZEPINE TOXICITY

Hepatic Encephalopathy

Hepatic encephalopathy is considered a reversible metabolic encephalopathy characterized by a spectrum of CNS effects. Symptoms may progress from confusion and somnolence to coma. One current hypothesis implicates an increase in GABAergic tone in the development of encephalopathy.^{7,63}

Animal studies of hepatic encephalopathy secondary to galactosamine or thioacetamide (hepatotoxins) demonstrate an increase in GABA effect, which is antagonized by flumazenil, bicuculline (a GABA receptor antagonist), and isopropylbicyclophosphate chloride (a calcium channel blocker).⁷ Cerebrospinal fluid (CSF) from these animals contained a benzodiazepine receptor ligand with agonist activity. Rat studies involving hepatic encephalopathy resulting from acute liver ischemia showed only a slight response to flumazenil, but significant improvement after administration of a partial inverse agonist.^{12,69}

Human studies have detected benzodiazepine binding activity in the CSF (but not in serum) of patients with hepatic encephalopathy. One group identified four to 19 peaks representing benzodiazepine binding ligands from the frontal cortex of 11 patients who died of hepatic encephalopathy.¹⁰ Two of the peaks were further characterized as diazepam and N-desmethyldiazepam. Brain concentrations of these substances were 2 to 10 times higher than normal in six of the patients and were normal in five patients. Patients with idiopathic recurring stupor who have measurable “endozepines” (endogenous benzodiazepine ligands) in serum and CSF are reported.^{58,66}

Flumazenil improves the clinical and electrophysiologic responses of patients with hepatic encephalopathy and idiopathic recurring stupor.^{4,8,19,58,66} Some patients with encephalopathy have improved from stage IV to stage II encephalopathy following IV flumazenil. Maximal improvement after flumazenil lasts approximately 1 to 2 hours and gradually dissipates within 6 hours. The response rate in a meta-analysis averaged approximately 30%.²⁹ The proposed explanations for the unresponsiveness include cerebral edema, hypoxia, other systemic diseases or complications, and irreversible CNS damage.

Animal and human data convincingly support the concept that increased GABAergic tone is responsible for hepatic encephalopathy. Evidence for endogenous benzodiazepine ligands that enhance GABA action also are demonstrated but controversial.^{1,3} The source of these benzodiazepine receptor agonists is unclear, but diet and/or production by gut bacteria is postulated.⁷ Most authorities believe endogenous de novo synthesis is unlikely and propose prior benzodiazepine exposure and persistence of clinical effects as an explanation. Hyperammonemia, neurosteroids, and hemoglobin metabolites are also implicated in the pathophysiology of hepatic encephalopathy.^{3,11,59}

Flumazenil can lead to short term improvement of the clinical condition of a subgroup of patients with hepatic encephalopathy and may prove useful as an addition to conventional therapy.^{2,4,9} Existing guidelines recommend use be reserved for patients with acute hepatic encephalopathy and a history of benzodiazepine use.^{11,22} Additional research is necessary to prospectively identify responders, provide dosing considerations, and evaluate adverse events. There is no known survival benefit.

Ethanol Intoxication

Animal studies indicate that many of the actions of ethanol are mediated through GABA neurotransmission.⁶⁵ Acute ethanol administration appears to enhance GABA transmission and inhibit N-methyl-D-aspartate excitation. Chronic ethanol administration leads to downregulation of the GABA system. Ethanol enhances GABA_A induced chloride influx in a dose-dependent fashion without a direct effect on chloride. Flumazenil does not influence this action of GABA. Chronic ethanol use selectively increases the sensitivity to inverse benzodiazepine agonists, invoking a change in coupling or conformation of the receptor. These changes may explain the development of tolerance and the kindling and production of seizures that occur on ethanol withdrawal.

A randomized, double-blind, crossover study of eight male volunteers given IV ethanol to achieve a constant serum ethanol concentration of 160 mg/dL was conducted.¹⁶ Once stabilized, the volunteers were given either placebo or 5 mg flumazenil. Subjective and objective psychomotor tests were conducted, with no differences noted between volunteers

given flumazenil and volunteers given placebo. Thus the probability of ethanol reversal at the doses achieved appears unlikely.

Based on this information, flumazenil likely does not have a significant effect on ethanol intoxication, and low doses of flumazenil (< 1 mg) have no effect.^{44,47} The 5 mg doses reportedly produce favorable changes in sensorium, but these findings may be the result of confounding factors. Because we would not administer 5 mg flumazenil in the overdose setting to avoid the increased risk of adverse effects at this dose, flumazenil cannot be recommended for reversal of ethanol intoxication.

ADVERSE EFFECTS AND SAFETY ISSUES

Flumazenil has been studied in more than 3500 patients worldwide, including healthy volunteers and overdosed patients, or patients who had undergone conscious sedation. The safety of flumazenil in healthy volunteers is well established, with no discernible objective or subjective effects. However, seizures in benzodiazepine-dependent patients, dysrhythmias in patients who coingest a benzodiazepine and a prodysrhythmic xenobiotic, and resedation within 20 to 120 minutes in patients receiving benzodiazepines for conscious sedation are recognized adverse events associated with flumazenil administration.

The ability of flumazenil to precipitate acute benzodiazepine withdrawal seizures in a more controlled environment than the overdose setting was demonstrated by reversal of long-term benzodiazepine sedation in the intensive care unit. A study of 1700 patients revealed that 14 patients developed adverse drug reactions—probably one-half of these reactions were related to abrupt arousal.⁶ Two patients with a history of epilepsy developed tonic-clonic seizures, and one patient developed myoclonic seizures.⁶ Dose-dependent induction of withdrawal reactions is therefore suggested. Small total doses (< 1 mg) of titrated flumazenil may allow sufficient occupation of the benzodiazepine receptor sites by benzodiazepines to limit the occurrence of withdrawal seizures.

In a study of 12 patients receiving midazolam sedation for 4 ± 3 days, 0.5 mg flumazenil was administered as a rapid bolus. Serum norepinephrine and epinephrine concentrations rose within 10 minutes, returned to baseline within 30 minutes, and correlated with increased heart rate, blood pressure, and myocardial oxygen consumption.³⁸

Flumazenil causes a significant overshoot in cerebral blood flow and may cause a large increase in intracranial pressure in patients who receive midazolam for severe head injury.⁷⁵

Thirty published case studies involving 758 patients with drug overdoses were reviewed.²⁵ In total, 387 patients participated in double-blind study protocols and 371 patients in open-label studies.²⁵ Fifty percent of cases were of mixed overdoses. The doses of flumazenil ranged from 0.2 to 5 mg. Five cases of seizures were temporally related to flumazenil administration, all after large bolus doses. In three of the five patients, high concentrations of tricyclic antidepressants were present in the blood. The seizures resolved either without treatment or following administration of a small dose of a benzodiazepine. Dysrhythmias developed in two patients given small doses of flumazenil, both presumably associated with the presence of a tricyclic antidepressant. Of 497 patients enrolled in two clinical US studies sponsored by the manufacturer,²⁵ six patients developed seizures (five had coingested tricyclic antidepressants) and one patient who had taken a tricyclic antidepressant and carbamazepine had a junctional tachycardia, which normalized after several minutes. Thus, in reviewing 1255 patients, 11 patients had seizures and three developed dysrhythmias, for an incidence of approximately 0.9%. The consensus report was that (a) flumazenil is not a substitute for primary emergency care, (b) hypoxia and hypotension should be corrected before flumazenil is used, (c) when used, small titrated doses of flumazenil should be given, (d) flumazenil should not be used in patients with a history of seizures, evidence of seizures or jerking movements, or evidence of a tricyclic antidepressant overdose, and (e) flumazenil should not be used by inexperienced clinicians.

An analysis of all seizures associated with flumazenil gathered from previously published cases or reports to the manufacturer was published.⁶⁴ Forty-three patients had seizures and six patients died, but the author believed that none of the deaths were attributable to flumazenil.⁶⁴ Four patients developed status epilepticus; two were presumed to be caused by concomitant tricyclic antidepressant exposure, and the other two patients had received benzodiazepines to treat status epilepticus prior to flumazenil therapy. In six of 43 seizure episodes, the relationship to flumazenil use was believed to be inadequately defined. The remaining 37 patients were stratified into five categories. In category 1, seven patients were given flumazenil after they had received a benzodiazepine for treatment of a seizure disorder. Six of these seven patients received greater than 1 mg flumazenil. In category 2, 20 patients received flumazenil for reversal of a benzodiazepine in a mixed-drug overdose. Many of these patients had coingested tricyclic antidepressants. Thirteen of these patients received more than 1 mg flumazenil. Two of the patients in this group developed status epilepticus and died, possibly secondary to a severe tricyclic antidepressant overdose. Category 3 included five patients who received benzodiazepines for suppression of non-drug-induced seizures. Two of these five patients received more than 1 mg flumazenil. Category 4 included three patients with acute benzodiazepine overdoses in the presence of chronic benzodiazepine dependence. Category 5 included two patients who received a benzodiazepine for conscious sedation. Therefore, flumazenil use may place the patient at risk

for seizures by unmasking a toxic effect in mixed overdose, by removing the protective anticonvulsant effect in a patient with non-drug induced seizures, or by precipitating acute benzodiazepine withdrawal. Table A22–3 summarizes the contraindications and precautions to flumazenil use.

TABLE A22–3. Contraindications to Flumazenil Use	
History	Clinical
Seizure history or current treatment of seizures	Potential ECG evidence of cyclic antidepressant use: terminal rightward 40 ms axis, QRS or QT prolongation
Ingestion of a xenobiotic capable of provoking seizures or cardiac dysrhythmias	Hypoxia or hypoventilation*
Long-term use of benzodiazepines	Hypotension
	Head trauma

* = do not rely on flumazenil to reverse benzodiazepine induced respiratory depression.

Flumazenil has not consistently reversed benzodiazepine induced respiratory depression and is not suggested as the initial intervention should respiratory depression occur.^{21,46,50,62} It is likely that following oral overdose, benzodiazepine-induced respiratory insufficiency is related to smooth muscle relaxation resulting in a mechanical effect with an increase in upper airway resistance and obstructive apnea rather than a central effect.³² Although flumazenil might improve the clinical situation,^{32,55} other standard procedures such as airway repositioning, supplemental oxygen, bag-valve-mask ventilation, and endotracheal intubation, if indicated, should be used either prior to or during reversal.

PREGNANCY AND LACTATION

Flumazenil is US Food and Drug Administration (FDA) pregnancy category C. There are no adequate studies done in pregnant women.²¹ It is not known whether flumazenil is excreted in breast milk.²¹

DOSING AND ADMINISTRATION

Slow IV titration (0.1 mg/min), and waiting one minute between doses, to a total dose no higher than 1 mg seems most reasonable. Administration into a large freely running vein minimizes the potential for pain at the injection site. Resedation may occur at 20 to 120 minutes, and readministration of flumazenil may be necessary. Although not approved by the FDA, continuous IV infusion of flumazenil 0.1 to 1.0 mg/h in 0.9% sodium chloride solution or 5% dextrose in water has been used following the loading dose.^{43,72,74}

FORMULATION

Flumazenil is available by many manufacturers in a concentration of 0.1 mg/mL with parabens in 5 and 10 mL vials.

SUMMARY

- The risks of flumazenil appear to greatly outweigh the potential benefits of reversal when benzodiazepines are used chronically or acutely to treat a seizure disorder.
- Flumazenil is best avoided in the overdose setting when evidence indicates coingestion of a drug capable of causing seizures or dysrhythmias.
- Flumazenil should also not be used when involvement of a tricyclic antidepressant is strongly suggested based on history, clinical findings, or findings on electrocardiography (prolonged QRS complex).^{35,45,51,70}
- Any indication that theophylline, carbamazepine, chloral hydrate, chloroquine, and or chlorinated hydrocarbons was ingested is a contraindication to flumazenil use.⁷⁰
- In the event of flumazenil induced seizure, a therapeutic dose of a benzodiazepine such as diazepam or lorazepam should be effective; however, due to the competitive nature of flumazenil, higher doses will be necessary to reverse higher doses of flumazenil.

75 SEROTONIN REUPTAKE INHIBITORS AND ATYPICAL ANTIDEPRESSANTS

Christine M. Stork

INTRODUCTION

In the United States, major depressive disorder is a leading cause of disability and affects 14.8 million American adults; it is also the largest cause of disability for adolescents and those 15 to 44 years of age.^{1,93} Although major depressive disorder can develop at any age, the median age at onset is 32 years and it is more prevalent in women.^{94,95} The exact etiology of depression and the mechanism by which increased serotonergic and norepinephrine neurotransmission modulates mood remains unclear. Antidepressants modulate the activity of serotonin and norepinephrine and dopamine to achieve their effect. The class of selective serotonin reuptake inhibitors (SSRIs) includes citalopram, escitalopram (active enantiomer of citalopram), fluoxetine, fluvoxamine, paroxetine, sertraline, and vilazodone (Fig 75–1). Atypical antidepressants extend the pharmacologic principles of SSRIs to achieve beneficial effects for patients with depression. The SSRIs and atypical antidepressants comprise the current standard for the treatment of depression.⁸⁰ SSRIs also are used to treat obsessive–compulsive disorders, panic disorders, alcoholism, obesity, and various nonpsychiatric disorders such as migraine headaches and chronic pain syndromes.^{11,125,131} They have excellent safety profiles when compared with monoamine oxidase inhibitors (MAOIs) and the cyclic antidepressants. Like many xenobiotics, the appropriateness of their use and the associated morbidity and mortality is questioned as the patient population has aged and the comorbidity profiles of those using the SSRIs have changed.

FIGURE 75–1. Structures of common selective serotonin reuptake inhibitors. Citalopram is shown as the S-enantiomer (escitalopram).

HISTORY AND EPIDEMIOLOGY

Serotonin (5-hydroxytryptamine) got its name after its initial discovery as a vasoconstrictor. Synonyms for 5-hydroxytryptamine include thrombotin, enteramin, substance DS, and 3-(β-aminoethyl)-5-hydroxyindole. SSRIs initially were marketed in the United States in the early 1980s and still are considered a first-line therapy for treatment of depressive disorders in the United States and Europe.⁶³ SSRIs are as effective as the cyclic antidepressants and MAOIs for the treatment of major depression and have fewer significant adverse events associated with their therapeutic use and are

less problematic in overdose (Chaps. 71 and 73). An increased risk of suicidal behavior is reported with the use of many antidepressants compared with herbals or counseling alone.¹⁰⁸ This is particularly true in children and adolescents, and may be related to delayed onset of therapeutic efficacy coupled with increased energy associated with the initiation of therapy.

PHARMACOLOGY

Table 75–1 lists the pharmacology, therapeutic doses, and metabolism of available SSRIs and atypical antidepressants. Modulation of serotonin and norepinephrine neurotransmission has a significant role in the treatment of depression.¹⁴⁶ There are seven widely known classes of serotonin receptors, with many exhibiting subtype classifications (Chap. 14). SSRIs selectively inhibit serotonin reuptake via the serotonin transporter due to the p-trifluoromethyl or p-fluoro substitution, present in many of these xenobiotics.¹⁸² Serotonin neurons are located almost exclusively in the median raphe nucleus of the brainstem, where they extend into and are in close proximity to norepinephrine neurons that are located primarily in the locus ceruleus (Fig. 75–2).¹⁰ The interplay between norepinephrine and serotonin likely explains the effectiveness of antidepressants that do not directly modulate serotonin neurotransmission.

TABLE 75–1. Drug Mechanism and Drug Information for Currently Available SSRIs and Atypical Antidepressants^a

Drug	Typical Daily Dose Range (mg)	<i>t</i> _{1/2} (hours)	Major Metabolic Enzyme	Major Active Metabolites	Major Active Metabolite <i>t</i> _{1/2}	Drug (s) or Metabolite (s) Inhibit CYP
SSRIs						
Citalopram (Celexa)	20–60	35–37	CYP19, 3A4, 2D6	Monodemethyl citalopram, didemethyl citalopram	59 hours	None/unknown
Escitalopram (Lexapro)	10–20	23–32	CYP19, 3A4, 2D6	S-(+)-Desmethylescitalopram	59 hours	None
Fluoxetine (Prozac) also sold as Sarafem	10–60	24–164	CYP2D6	Normofluoxetine	4–16 days	2D6 (d,l), CYP19 (d,l), 2D6 (d,l), 3A4 (m)
Fluvoxamine (Luvox)	100–300	15–29	1A2, 2D6	None	N/A	1A2, CYP19, 3A4
Paroxetine (Paxil)	10–50	23–44	2D6	None	N/A	2D6
Sertraline (Zoloft)	50–200	24	CYP19, 2D6, CYP19, 2D6, 3A4	Desmethysertraline	62–104 hours	CYP19 (d,l)
Venlafaxine (Effexor) also partial serotonin 5-HT _{2A} agonist	10–60	25	3A4, CYP19, 2D6	None	N/A	None/unknown
SSRI with α_1-adrenergic antagonism						
Trazodone (Desyrel)	50–600	5–9	2D6, 3A inhibition may increase concentration	Meta-chlorophenylpiperazine	?	None/unknown
SSRI with inhibition of reuptake of norepinephrine						
Desvenlafaxine (Provig)	50	11	CYP2D6, 2D6	None, unknown	N/A	None/unknown
Duloxetine (Cymbalta)	40–60	8–17	2D6, 1A2	None	N/A	2D6
Milnacipran (Savella)	25–200	8	Glucuronidation	None	N/A	None
Venlafaxine (Effexor)	75–225	3–4	2D6	O-desmethylenefluoxetine, depends on 3A4 and CYP19 for metabolism	10 hours	None/unknown
SSRI with α_1-adrenergic antagonism 5-HT_{2A}/5-HT_{2C} antagonist						
Mirtazapine (Remeron)	15–45	20–40	3A4	Desmethylnortazapine	Unknown	3A4 induction
Inhibition of reuptake of biogenic amines or dopamine						
Bupropion (Wellbutrin, Zyban)	150–450	9.6–20.9	2D6	Hydroxybupropion, erythrohydroxybupropion, thiohydroxybupropion	24–37 hours	None/unknown

^aThe *t*_{1/2} of all these compounds is large enough to consider.

SSRIs = selective serotonin reuptake inhibitors.

FIGURE 75–2. Neuroanatomy and effects of several common therapeutic drugs on serotonin neurotransmission in the brain. (Xenobiotics in green are agonists and those in red are antagonists.) NRIs = nonspecific reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors.

PHARMACOKINETICS AND TOXICOKINETICS

The SSRIs display diverse elimination patterns and have numerous active metabolites, which substantially increase both the duration of therapeutic effectiveness and the duration during which drug interactions and adverse drug effects can occur after the medication is discontinued (Table 75–1). Important pharmacokinetic and pharmacodynamic drug interactions are reported with therapeutic dosing (see Serotonin Toxicity). The SSRIs and their active metabolites are substrates for—and potent inhibitors of—CYP2D6 and other CYP isoenzymes.^{73,147} For example, fluoxetine, fluvoxamine, citalopram, venlafaxine, mirtazapine, paroxetine, and sertraline are substrates for CYP2D6, whereas paroxetine, norfluoxetine, and fluoxetine inhibit the same enzyme (Table 75–1). Alternatively, mirtazapine induces CYP3A4 enzymes, while trazodone and vilazodone metabolism may be decreased after this same enzyme is inhibited.^{160,163} The consequences of these interactions manifest when the metabolism of medications that rely on these enzymes for metabolic transformation is altered (Chap. 13). Genetic polymorphism typing holds promise in identifying patients at highest risk for both adverse drug events and antidepressant efficacy with therapeutic dosing.^{90,91}

PATHOPHYSIOLOGY

The causes of depression and mechanism by which antidepressants ameliorate depressive symptoms are not well understood. Some postulated causes of depression include decreased neuronal serotonin storage, decreased synaptic serotonin, increased serotonin receptor sensitivity, and serotonin over activity resulting in depressed dopamine neurotransmission.^{146,162,176,181} Others postulate that physiologic stress and associated atrophy of dendritic processes with a loss of neurons and glial elements occur.¹⁶ These changes were most pronounced in the prefrontal cortex and the hippocampus on autopsy of depressed patients. It is unclear how these changes occur, although it is likely that complex signaling pathways including disruptions in synaptic proteins and synaptic activity are contributory. In addition to the direct pharmacologic effect of increasing synaptic concentrations of serotonin, antidepressants increase neurogenesis in the prefrontal cortex and glia in oligodendrocytes and activate complementary factors such as brain derived neurotrophic factor and mitogen-activated protein kinase. The requirement for these endogenous mediators may explain previous research

finding no difference in the concentration of serotonin-binding sites or serotonin receptor activity between depressed patients who respond to SSRIs and those who do not respond.^{31,151} Although the causes of depression are diverse and not well understood, genetic polymorphisms of the serotonin transporter may also be involved with individual responses to SSRI therapy.¹⁴² Unlike cyclic antidepressants and other atypical antidepressants, SSRIs have little direct interaction with cholinergic receptors, γ -aminobutyric acid receptors, sodium channels, or adrenergic reuptake (Table 75–2).

TABLE 75–2. Receptor Activity of SSRIs and Related Antidepressants

CLINICAL MANIFESTATIONS

Most effects that occur following overdose are direct extensions of the pharmacologic activity of SSRIs in therapeutic doses. Excess serotonergic stimulation is prominent and nonselective. Acute signs and symptoms include nausea, vomiting, dizziness, blurred vision, and, less commonly, central nervous system (CNS) depression and sinus tachycardia.^{26,28} Seizures and changes on electrocardiography (ECG), including prolongation of the QRS complex and QT interval duration, have been reported, but they rarely occur with most SSRIs, even after large overdoses (Table 75–3).^{88,143} Infrequently, SSRI overdose results in life-threatening effects. In two fatalities, the patient reportedly ingested 40 to 75 times the maximum daily dose of fluoxetine. Serum fluoxetine concentrations were 4500 and 6000 ng/mL, with the latter including a measured norfluoxetine concentration of 5000 ng/mL, which was more than 10 times higher than the therapeutic steady state serum.^{38,97}

SSRI = selective serotonin reuptake inhibitor.

Citalopram

Citalopram and its S(+) enantiomer escitalopram cause QT interval prolongation and seizures in a dose-related manner.¹⁷³ These effects are reported at doses as low as 400 mg for citalopram and 190 mg for escitalopram.^{35,185} In large case series, these effects typically occur after ingestions exceeding 600 mg citalopram or in patients with serum concentrations more than 40 times the expected therapeutic concentrations.^{74,138,139} In two of these series, seizures were an early finding, occurring within 2 hours, whereas the development of abnormalities on ECG were delayed for as long as 24 hours following ingestion.^{86,139} One case report, with concentrations at least 10 times the maximum therapeutic serum concentrations, documented prolongation of the QT interval and torsade de pointes occurring 32.5 hours after ingestion. Concentrations of citalopram and desmethylcitalopram were 477 mg/mL and 123.2 mg/mL, respectively.¹⁷¹

Although the mechanisms are unclear, experimental models suggest that the didesmethylcitalopram metabolite of citalopram prolongs the QT interval by blocking I_{Kr} , whereas high concentrations of both the parent drug and this metabolite result in seizures (Chaps. 16 and 64).^{25,32} The elimination half-life of the R-enantiomer of citalopram exceeds that of the S-enantiomer.¹⁷⁷ The implications of this difference on the formation and effects of racemic forms of didesmethylcitalopram are unclear.

Vilazodone

Vilazodone is a relatively new SSRI that is also a 5-HT_{1a} agonist. Although little data exist regarding vilazodone in overdose, the drug is expected to have similar effects to other SSRIs.²

MANAGEMENT

Treatment of patients with acute SSRI overdose is largely supportive. Dextrose and thiamine should always be considered for patients who present with altered mental status. Although cardiac manifestations after SSRI overdose are rare, a 12-lead ECG should be obtained to identify other cardiotoxic drugs, such as cyclic antidepressants, to which the patient may have access (Chaps. 16, 70, and 71). If overdose of citalopram or escitalopram is suspected, then 24 hours of cardiac monitoring is recommended to exclude the possibility of delayed QT interval prolongation and subsequent risk for ventricular dysrhythmias. After the patient is stabilized, oral activated charcoal (1 g/kg) may be useful to adsorb drug remaining in the gastrointestinal tract. In fact, lowering of blood concentrations and reduction in risk for QT interval prolongation is demonstrated when activated charcoal is given shortly after escitalopram and citalopram ingestion.^{58,59,174} Patients with small unintentional overdoses of SSRIs other than citalopram and escitalopram are not expected to develop

significant signs and symptoms of poisoning. Patients with well defined unintentional ingestions of up to 100 mg of citalopram and 50 mg of escitalopram can usually be managed safely at home with close observation.¹²⁷ Fatalities resulting from SSRIs are rare and most commonly occur after multiple drug ingestions and manifestations of drug interactions resulting from excess serotonergic effects (see Serotonin Toxicity).⁶⁸ Forensic analysis of individual cases of intentional ingestions suggests the minimum lethal concentrations of fluoxetine, paroxetine, and sertraline after isolated overdose are 0.63, 0.4, and 1.5 mg/L, respectively. Postmortem concentrations in case reports include a citalopram heart blood concentration of 3.35 mg/L, a whole blood concentration of 11.6 mg/L, and urine concentrations of 32.43 to 149.67 mg/L.^{84,114} When mono-N-desmethylcitalopram was measured, concentrations of 1.02 mg/L were found in the blood and 12.1 mg/L in the urine. An infant survived with citalopram plasma mono-N-desmethylcitalopram concentrations of 1.4 mg/L.¹¹⁷

ADVERSE EVENTS AFTER THERAPEUTIC DOSES

Adverse events commonly associated with therapeutic doses of SSRIs as well as with overdose include gastrointestinal symptoms such as anorexia, nausea, vomiting, diarrhea, sexual dysfunction—in both men and women—headache, insomnia, jitteriness, dizziness, and fatigue.¹⁸³ Less common adverse events include sedation, particularly following citalopram and paroxetine, which result from their weak anticholinergic activity, and anxiety following fluoxetine treatment.¹¹⁰ Serotonin activity inhibits platelet secretory response, platelet aggregation, and platelet plug formation.²¹ Although the effect increases in SSRIs with increased potency, clinical bleeding is rare, and significant only in patients concurrently on other antiplatelet medications, most notably aspirin.^{34,36} This effect may be of potential benefit in patients at risk for cardiovascular events.¹¹⁸ Other rarely reported adverse events include new-onset panic disorder, priapism, bradycardia, hepatotoxicity, and urinary incontinence.^{4,20,29,48,100,122,164} Movement disorders, most commonly akathisia, parkinsonism, myoclonus, and dystonia, also occur after SSRI use.^{7,154} These extrapyramidal adverse events may be related to the complex interplay between serotonergic and dopaminergic activity. Predisposing factors for the development of movement disorders include concomitant use of dopamine antagonists such as the antipsychotics.¹⁰⁴

The syndrome of inappropriate antidiuretic hormone (SIADH; Chap. 19) in which severe hyponatremia may occur rapidly is associated with SSRI use. In an animal model, the effect appears to be serotonin mediated, with increased concentrations of serum cortisol, adrenocorticotropin, and vasopressin reported.⁶¹ Rat studies demonstrated that stimulation of 5-HT_{1C} receptors increases antidiuretic hormone secretion.¹³⁷ However, human case control studies have not confirmed defects in osmoregulated release of vasopressin using water loading tests and measurement of vasopressin concentrations after 3 to 11 months of paroxetine use.¹¹⁶ A review of the literature identified women older than 70 years concomitantly receiving diuretic therapy and with low baseline serum sodium concentrations were at greatest risk for developing SIADH.^{22,98} Although reported to occur from 3 days to 4 months after initiation of therapy, a case-matched control study of 203 patients identified that SIADH occurs most frequently within the first 2 weeks of therapy.¹²¹ Hyponatremia may occur when switching from one SSRI to another.⁹ Efforts to predict risk through poor CYP2D6 genotype metabolizer status or high serum concentrations have not been successful.¹⁶⁷ Patients older than 50 years of age using SSRIs may be at increased risk for bone fracture presumably due to a serotonergic effect on osteoblasts and osteoclasts.¹⁴⁵ However, depression itself is also implicated in decreasing bone density in adults and children and the implications of these findings are unknown.¹⁷⁹

Serotonin Toxicity

The most common severe adverse event associated with SSRIs is the development of the serotonin toxicity. This is also referred to in life-threatening cases as serotonin syndrome and serotonin behavioral or hyperactivity syndrome. It was first described in patients treated with MAOIs who were given other xenobiotics that enhance serotonergic activity.^{37,72,130,161} However, ingestion of an MAOI is not required for serotonin toxicity to develop, and its occurrence is unpredictable (Table 75–4).

Pathophysiology. The pathophysiologic mechanism of serotonin toxicity is not completely understood but involves excessive selective stimulation of serotonin 5-HT_{2A} and perhaps 5-HT_{1A} receptors.²⁷ Animal models demonstrate that specific stimulation of 5-HT_{1A} receptors results in signs and symptoms of serotonin toxicity even when 5-HT_{2A} receptors were inactivated using a specific antagonist.⁴¹ However, a subsequent animal study and a human retrospective case series showed that the potency of 5-HT_{2A} antagonist therapy was directly related to resolution of the findings attributed to serotonin toxicity.⁶⁵ 5-HT_{1D} receptors are not implicated in cases of serotonin toxicity.

Serotonin toxicity occurs most frequently following use of combinations of serotonergic xenobiotics (Table 75–4), but may occur following high therapeutic dosing or overdoses of single serotonergic xenobiotics.^{40,77,92,133} Interactions resulting in serotonin toxicity can occur while switching serotonergic xenobiotics, particularly when an insufficient time lag occurs before initiating the alternative therapy.¹¹² Residual pharmacologic effects, receptor downregulation or upregulation, and the presence of active metabolites may be causative in these circumstances. For example, fluoxetine metabolism results in the active metabolite norfluoxetine, which has comparable pharmacologic effects and a half-life substantially longer than fluoxetine. The clearance of norfluoxetine takes approximately 2 weeks.

Although sporadic reports occur, selective MAO subtype B (MAO-B) inhibitor drug combinations and triptans (5-HT_{1B/1D} receptor agonists) are rarely reported to result in serotonin toxicity at therapeutic doses.^{53,56}

Manifestations. Signs of serotonin toxicity include altered mental status, agitation, tachycardia, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, incoordination, muscle rigidity, and hyperthermia (Table 75–5). The clinical manifestations of serotonin toxicity are diverse, and minor manifestations are common after initiation of SSRI and atypical antidepressant therapy. In fact, a prospective study of depressed inpatients given clomipramine demonstrated that 16 of the 38 patients experienced manifestations consistent with the serotonin toxicity, with 14 having spontaneously resolution within one week without discontinuation of therapy.¹⁰⁷ Life-threatening effects invariably result from hyperthermia caused by excessive muscle activity that may be more prominent in the lower extremities. Sustained severe hyperthermia can lead to death through denaturation of essential protein and enzymatic function that ultimately results in elevated lactate and metabolic acidosis, rhabdomyolysis, renal and hepatic dysfunction, disseminated intravascular coagulation, or acute respiratory distress syndrome (Chap. 30).^{120,169}

TABLE 75–5. Diagnostic Criteria for Serotonin Toxicity

When a Serotonergic Xenobiotic Is Introduced

- Spontaneous clonus alone
- [Inducible or ocular clonus] with [agitation or diaphoresis]
- [Inducible or ocular clonus] with hypertonicity and fever (temperature > 100.4°F {38°C})
- Tremor with hyperreflexia

Adapted from Dunkley et al.⁵²

Diagnosis. Although fulminant life-threatening cases are easy to recognize, mild cases of serotonin toxicity are more difficult to distinguish from similar appearing disorders due to other causes. In an effort to determine diagnostic criteria, a study that included 38 cases of presumed serotonin toxicity suggested diagnostic criteria to include three of the following signs and symptoms—altered level of consciousness, agitation, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, and incoordination—when other etiologies were excluded.¹⁶⁹ A modification, the Hunter Serotonin Toxicity Criteria, which included the variables myoclonus, agitation, diaphoresis, hyperreflexia, hypertonicity, and fever, was validated in 473 patients and found to correlate best with a clinical toxicologic diagnosis of serotonin toxicity (Table 75–5).⁵² Currently, no diagnostic test capable of determining whether a patient is experiencing serotonin toxicity is available. A single case report demonstrated increased urinary serotonin concentrations after serotonin toxicity.³⁹

Management. Treatment of patients with serotonin toxicity begins with supportive care and focuses on decreasing core body temperature and muscle activity. Because muscular rigidity is thought to be greatly responsible for hyperthermia and death, rapid external cooling in conjunction with aggressive use of sedative hypnotics such as benzodiazepines should limit complications and mortality (Chap. 30). In severe cases, neuromuscular blockade should be considered to achieve rapid muscle relaxation. The time course of the serotonin toxicity is variable and related to the time required to eliminate the offending xenobiotics. In most patients, the manifestations of serotonin toxicity resolve within 24 hours after the offending xenobiotic is removed. However, serotonin toxicity can be prolonged when it is caused by xenobiotics with long half-lives, protracted duration of effects, or active metabolites.

Animal models indicate that pretreatment with serotonin antagonists can prevent development of serotonin toxicity.^{64,83,165} Several case reports indicate the successful use of 4 mg oral cyproheptadine, an antihistamine with nonspecific serotonin antagonist effects at 5-HT_{1A} and 5-HT_{2A} receptors.^{72,105} Patients who typically responded had no hyperthermia and mild to moderate manifestations of serotonin toxicity. Evidence supports the use of cyproheptadine in this patient group. Current recommendation suggests doses of 8 to 16 mg orally repeated as needed. Further research is warranted to determine the success of higher doses given to gain sufficient 5-HT_{2A} antagonistic effects in more severely affected patients.⁶⁵ Other xenobiotics anecdotally reported to be successful for the treatment of symptoms caused by serotonin toxicity include methysergide, chlorpromazine, atypical antipsychotics, and propranolol.^{65,66,69,75,150} However, these therapies cannot be recommended at this time.

Differentiating Serotonin Toxicity from Neuroleptic Malignant Syndrome

Many features overlap between serotonin toxicity and the neuroleptic malignant syndrome (NMS; Chap. 70). Some authors call these “spectrum disorders” caused by drugs with antidopaminergic effects, proserotonergic effects, or both.¹⁶⁸ This position is supported by the finding that 5-HT_{2A} agonism results in an overall decrease in neuronal dopamine release. Some authors also report NMS after use of serotonin-enhancing xenobiotics. However, low concentrations of measured dopamine and normal concentrations of serotonin metabolites in NMS patients support the hypothesis of central dopaminergic hypoactivity in NMS.^{12,128} Although altered mental status, autonomic instability, and changes in neuromuscular tone that may result in hyperthermia are common to both disorders, many differences are apparent. It is now clear that the implicated xenobiotics, time course, pathophysiology, and manifestations are distinct (Table 75–6).⁶⁵ Signs and symptoms of serotonin toxicity develop within minutes to hours after exposure to the offending xenobiotics, whereas NMS typically develops days to weeks after daily exposure.⁷¹ In addition, after symptoms develop and offending xenobiotics are discontinued, NMS can last for as long as 2 weeks, whereas serotonin toxicity usually resolves quickly, and is directly correlated with the pharmacokinetic metabolic profile of the offending xenobiotic. A review of the literature indicates that patients presenting with serotonin toxicity are more likely to exhibit agitation, hyperactivity, clonus and myoclonus, ocular oscillations (opsoclonus), shivering, tremors, and lower limb hyperreflexia, whereas patients presenting with NMS were more likely to exhibit bradykinesia and lead pipe rigidity.⁶⁵

– = not found; + = rare finding; +++ = common finding.

ATYPICAL ANTIDEPRESSANTS

Atypical antidepressants are defined as not belonging strictly to a set classification of antidepressants. They are not SSRIs, cyclic antidepressants, or MAOIs. Most are derivatives of SSRIs and have additional pharmacologic effects that were

selected in an attempt to decrease the undesirable side effects of traditional antidepressants.

Serotonin/Norepinephrine Reuptake Inhibitors

Venlafaxine.

In addition to inhibiting serotonin reuptake, venlafaxine inhibits norepinephrine reuptake. Venlafaxine produces rapid downregulation of central β -adrenergic receptors, which may result in a faster onset of antidepressant effect.¹⁵⁶ Patients with acute venlafaxine overdose may present with nausea, vomiting, dizziness, tachycardia, CNS depression, hypotension, hypoglycemia, hyperthermia, hepatic toxicity, including zone 3 necrosis, rhabdomyolysis, and seizures^{57,134,158,180,186} (Chap. 23). Sodium and potassium channel blocking effects are rarely clinically apparent; however, QRS prolongation and QT prolongation may lead to ventricular tachycardia and result in death.^{17,24,149} One report indicated a positive incremental association of clinical toxicity with a maximum measured venlafaxine serum concentration of 25.8 $\mu\text{mol/L}$.¹¹⁹ Although no clinical data regarding efficacy are available, sodium bicarbonate may be helpful in attenuating the sodium channel blocking effects that leads to QRS prolongation (Antidotes in Depth: A5). In addition, gastrointestinal decontamination with activated charcoal with or without whole-bowel irrigation may decrease serum concentrations and decrease the incidence of seizures in select patients, particularly following the ingestion of extended-release formulations.^{102,103} Adverse events associated with chronic therapeutic doses of venlafaxine include alopecia, yawning, focal myositis facial flushing, and dose-related increases in blood pressure.^{46,49,54,87,136}

Desvenlafaxine, duloxetine, and milnacipran—similar drugs to venlafaxine—should be expected to have similar effects.^{51,101,109}

Other Atypical Antidepressants with Reuptake Inhibition as Part of Their Mechanism

Bupropion.

The use of bupropion, especially extended-release formulations, is common for the treatment of depression. Bupropion is also frequently used as in the treatment of smoking cessation therapy, attention deficit hyperactivity disorder, and, occasionally, in compulsive eating disorders.^{5,115} The pharmacologic mechanism of action of bupropion, a substituted cathinone (β -keto amphetamine) and its active metabolite, hydroxybupropion, include inhibition of the release and reuptake of dopamine and, to a lesser extent, serotonin and norepinephrine.⁸ Chronic doses above 450 to 500 mg/day place patients at risk for seizure.^{43,89} Frequent effects that occur following overdose include tachycardia, hypertension, gastrointestinal symptoms, and agitation.^{15,18} Large acute overdoses may result in seizures, QRS prolongation, or both.^{67,79,132,159} In some cases, effects were delayed for up to 10 hours, and seizures up to 24 hours, particularly following the ingestion of sustained-release preparations.^{78,159,166} Symptoms can continue for up to 48 hours.

Studies are conflicting as to whether seizures are caused by bupropion or its metabolite hydroxybupropion.^{60,140} Elevated bupropion and hydroxybupropion concentrations are documented after seizures. The exact mechanism for seizures caused by hydroxybupropion is unclear at this time.^{43,60,89,148} Treatment, when required for seizures, should be supportive

and includes judicious use of benzodiazepines. QRS prolongation is likely due to gap junction dysfunction and therefore may not be uniformly responsive to sodium bicarbonate (Antidotes in Depth: A5). Bupropion is a lipophilic drug with a logP of 3.47 and a logD at pH 7 of 3.08. These physiochemical characteristics and the ability of bupropion to effect myocardial conduction have led to the proposed use of intravenous fat emulsion after overdose. Intravenous fat emulsion therapy was used to successfully resuscitate a 17 year-old woman who ingested multiple drugs including bupropion even after sodium bicarbonate and advanced life support failed and should be considered in similar cases (Antidotes in Depth: A20).¹⁵⁹ Early after an overdose of sustained-release bupropion, activated charcoal should be considered, with use of multiple doses of activated charcoal or possibly whole-bowel irrigation after large, potentially life-threatening ingestions.

Other serious adverse events reported following chronic bupropion use include cholestatic and hepatocellular dysfunction and rhabdomyolysis, with isolated reports of chest pain, dystonia, trigeminal nerve dysfunction, mania, generalized erythrodermic psoriasis, erythema multiforme, dyskinesia, altered vestibular and sensory function, and serum sickness.^{6,39,42,45,50,70,96,111,172,184}

Trazodone.

Trazodone is an antagonist at 5-HT₂ receptors, a partial agonist at 5-HT₁, and a weak serotonin reuptake inhibitor. In addition, trazodone has peripheral α -adrenergic antagonist activity. CNS depression and orthostatic hypotension are the most common complications after acute overdose of trazodone.⁶² Trazodone is rarely reported to cause SIADH. This effect may be responsible for seizures, which rarely occur after acute overdose.^{13,175} Rarely, cardiac conduction delays are also reported following overdose.¹⁵⁷ Priapism, reported with trazodone, may occur occasionally after overdose.⁶² Management of hypotension includes supportive care and administration of fluids and vasopressors, if necessary.

Mirtazapine.

The mechanism of action of mirtazapine is unique. In addition to serotonin reuptake inhibition, mirtazapine increases neuronal norepinephrine and serotonin through α_2 -adrenergic antagonism.⁴⁴ Mirtazapine also blocks some subtypes of 5-HT receptors, including 5-HT₂ and 5-HT₃, which may have antidepressive effects.¹²⁹ The main effects that occur after acute mirtazapine overdoses include altered mental status, tachycardia, and hypothermia.^{113,178} Large overdoses may cause respiratory depression and prolongation of the QT interval.^{30,144} Rare adverse reactions associated with the therapeutic use of mirtazapine causing serotonin toxicity, hepatitis, hypertension, and reversible agranulocytosis is reported.^{3,81,85,126}

DRUG DISCONTINUATION SYNDROME

The term “drug discontinuation syndrome” is used to describe the physiologic manifestations that occur after abrupt antidepressant cessation. The choice of terminology between withdrawal syndromes and drug discontinuation syndromes is unclear, but they may relate to the manifestations occurring after therapeutic use versus misuse, that is, alcohol or heroin withdrawal and SSRI discontinuation syndrome. Drug discontinuation syndromes are commonly reported after abrupt discontinuation of conventional antidepressants, including cyclic antidepressants and MAOIs (Chaps. 71 and 73).¹⁰⁶ SSRIs cause a discontinuation syndrome that typically begins within 5 days after drug discontinuation and may last up to 3 weeks.⁷⁶ The most frequently reported symptoms include dizziness, lethargy, paresthesias, nausea, vivid dreams,

irritability, and depressed mood.¹⁵³ The risk factors associated with development of a discontinuation syndrome are not fully clarified; however, in a given individual, a genetic polymorphism of the 5-HT_{1A} receptor may play a role.¹²⁴ The syndrome is more common with SSRIs with shorter elimination half-lives (paroxetine > fluvoxamine > sertraline > fluoxetine). In addition, SSRIs with high-potency serotonin reuptake inhibition are more frequently implicated (paroxetine > sertraline > clomipramine > fluoxetine > venlafaxine > trazodone). Of the SSRIs, paroxetine most often results in a discontinuation syndrome, which is mild to moderate in 20% to 40% of patients receiving 20 mg daily.¹⁴ Several studies demonstrate that the vast majority of cases are attributed to paroxetine with an approximately 20% risk with sertraline, venlafaxine, and escitalopram and 10% risk with fluvoxamine.^{14,23} Fluoxetine discontinuation syndrome occurs less frequently, at only two cases per 1 million prescriptions.¹⁴¹ The long elimination half-life of fluoxetine and its active metabolite norfluoxetine probably decrease the incidence of discontinuation syndrome by providing a tapered effect following cessation.

Because of difficulty in distinguishing symptoms of discontinuation syndrome from underlying disease, many authors have proposed diagnostic criteria for the SSRI discontinuation syndrome.²³ All proposed criteria include discontinuation of the SSRI in concordance with CNS effects, gastrointestinal distress, or anxiety.¹⁷⁰ The prominent CNS findings include dizziness, ataxia, vertigo, sensory abnormalities, including electric shocklike sensations and paresthesia, and behavior abnormalities, including aggression and impulsivity.

The biochemical basis of the discontinuation syndrome appears to be similar to tryptophan depletion, which results in an acute decrease in synaptic serotonin.⁴⁷ In fact, abrupt discontinuation versus drug taper was a noted risk factor in paroxetine cases when compared with those who did not experience discontinuation symptoms.⁸² Although postulated, antimuscarinic withdrawal seems an unlikely cause because the antimuscarinic effects of desipramine failed to protect against paroxetine withdrawal in a human model.⁵⁵

Treatment of patients exhibiting the discontinuation syndrome should include supportive care and resumption of the discontinued drug or administration of another SSRI if the implicated drug is contraindicated.¹⁵² The drug then should be tapered at a rate that allows for improved patient tolerance. Many of the other antidepressants discussed in this chapter also result in discontinuation reactions. Symptoms appear similar to those reported following discontinuation of SSRIs and are treated in a similar manner.¹⁹

SUMMARY

- In acute overdose SSRIs or atypical antidepressants usually are not life threatening, although some produce seizures or cardiac toxicity. The management of these patients frequently is complicated because these patients likely have access to more life-threatening antidepressants such as tricyclic antidepressants and MAOIs.
- Monitoring for 24 hours is recommended for the delayed cardiotoxicity with citalopram or escitalopram as well as for delayed seizures following extended release bupropion ingestion.
- Drug interactions and adverse drug events are associated with serotonin reuptake inhibitors and may lead to acute life-threatening events, including serotonin toxicity.
- Serotonin toxicity can produce life-threatening hyperthermia and should be treated with aggressive cooling and sedation. Cyproheptadine may be useful in early cases, and neuromuscular blockade may be necessary in refractory cases.

H. SUBSTANCES OF ABUSE

CASE STUDY 6

History Police were called to a public area where an adolescent man was shirtless and acting bizarrely. It was a hot summer day with a temperature of 92°F (33°C) and a dew point of 75°F (24°C). The man, who appeared confused, was pacing and gesturing as if he was hallucinating. When the police approached him, he began to run away, but after a struggle he was subdued. The paramedics were called because of his behavior. When they arrived, they found an agitated and confused young man whose arms and legs were restrained and in a full-body bag. He was diaphoretic with 6 to 7 mm pupils, and he was breathing rapidly and had a pulse of 180 beats/min. Because of the restraints, no other vital signs were obtained, and the patient was transported to the emergency department (ED).

Immediate Assessment and Management On arrival at the ED, a team of physicians, nurses, and hospital security personnel were able to remove the patient from the body bag, restrain him, and transfer him to a hospital stretcher. An arm was held in place, and an intravenous (IV) line was inserted. Blood was obtained for analysis, and midazolam (10 mg IV) was given. Within a few moments, the patient became more calm, and the following vital signs were obtained: blood pressure, 198/122 mm Hg; pulse, 188 beats/min; respiratory rate, 38 breaths/min; tympanic temperature, 104.6°F (40.3°C); oxygen saturation, 98% on room air; and glucose, 187 mg/dL. Physical examination revealed a diaphoretic young man who was mumbling incoherently and was hot to the touch. There were no signs of trauma, and his pupils were 7 mm and reactive to light. His chest was clear, and his heart was regular and tachycardic without extra sounds. His abdomen was soft and nontender with normal bowel sounds. Although a complete neurologic assessment was not performed, he was disoriented, distracted, and unable to follow commands. His pupils were reactive, and oculoccephalic reflexes were present. Muscle tone was increased symmetrically and reflexes were brisk, with three to four beats of clonus noted at both ankles. His toes were down-going.

What Is the Toxicological Differential Diagnosis? This patient presents with agitation, tachycardia, hypertension, hyperthermia, diaphoresis, mydriasis, and disorientation. While this presentation is fairly characteristic of a sympathomimetic toxic syndrome (Chaps. 3, 76, and 78) additional considerations must include alcohol and sedative-hypnotic withdrawal (Chaps. 15 and 81), hallucinogens (Chap. 82), and phencyclidine (Chap. 86). These and other etiologies for the hyperthermia are listed in Table CS6–1.

TABLE CS6–1. Xenobiotics and Interactions Associated with Life Threatening Hyperthermia

Alcohol withdrawal	Oxidative phosphorylation uncouplers
Anticholinergics (atropine, antihistamines)	(dinitrophenol, salicylates)
Malignant hyperthermia	Phencyclidine
Monoamine oxidase inhibitor overdose	Sedative-hypnotic withdrawal
Neuroleptic malignant syndrome	Serotonin toxicity
	Sympathomimetics (cocaine, amphetamines)

What Immediate Interventions Are Required? A rectal probe was inserted, and the patient's core temperature was noted to be 109.2°F (42.9°C). This single vital sign abnormality takes precedence over the others and requires emergent intervention regardless of the etiology. An additional 5 mg of IV midazolam was administered (Antidotes in Depth: A23) to further control the agitation, and the patient was placed in an ice-water bath (Chap. 30). While in the bath, another 5 mg of midazolam was needed to control his behavior. One liter of 0.9 sodium chloride was infused through the peripheral IV line, and a Foley catheter was inserted, which drained a scant amount of dark yellow urine.

Within 15 minutes, the patient's core temperature fell to 101.4°F (38.6°C); he was removed from the ice bath; dried; and placed on a clean, dry stretcher. At that time, the following vital signs were obtained: blood pressure, 148/94 mm Hg; pulse, 120 beats/min; respiratory rate, 24 breaths/min; core temperature, 99.2°F (37.3°C); oxygen saturation, 96% on room air; end-tidal carbon dioxide, 46 mm Hg.

What Rapid Clinical and Laboratory Analyses Can Help Exclude Life-Threatening Consequences of This Patient's Presentation? The consequences of hyperthermia include injury to many organ systems as outlined in Table CS6–2. An electrocardiogram (ECG) should be obtained, as it can rapidly detect critical myocardial injury and life-threatening electrolyte abnormalities. A rapid assessment of electrolytes, kidney and liver function, coagulation status, acid–base balance, creatine kinase, troponin, and a urinalysis are all indicated. Severe abnormalities should be addressed as detected. In this case, although the urine dipstick showed the large presence of blood, the urine was clear,

leading to a clinical suspicion of rhabdomyolysis. The patient was started on fluids at twice his maintenance requirement as well as a bicarbonate infusion (Antidotes in Depth: A5).

TABLE CS6–2. Major Organ System Complications of Hyperthermia

Organ System	Complication
Brain	Cerebral edema
Lungs	Acute respiratory distress syndrome
Heart	Myocardial stunning, Myocardial infarction
Gastrointestinal	Hepatic injury
Kidneys	Acute kidney injury
Hematological	Coagulopathy
Muscle	Rhabdomyolysis

Further Diagnosis and Treatment The patient remained calm and began to answer questions a few hours later. The ECG showed sinus tachycardia with normal intervals and no pattern of injury. However, the laboratory results were remarkable for a creatinine of 3.4 mg/dL, a bicarbonate of 12 mEq/L, an anion gap of 30 mEq/L, and a creatine kinase of greater than 100,000 IU/L. Although repeat electrolytes showed a rapid correction of the bicarbonate and anion gap, the creatinine continued to rise and the creatine kinase remained greater than 100,000 IU/L. A nephrology consult was obtained because of the potential need for hemodialysis, but the patient continued to have an adequate urine output and urine electrolytes demonstrated a retained ability to concentrate the urine.

The patient regained a normal mental status and related that the last thing he remembered was smoking crack cocaine. Over the course of a week, the creatine kinase fell, and the serum creatinine stabilized at 1.7 mg/dL. A referral was made to an outpatient detoxification center, and the patient was discharged.

76 AMPHETAMINES

David H. Jang

HISTORY AND EPIDEMIOLOGY

Amphetamine is the acronym for racemic β -phenylisopropylamine or α -methylphenylethylamine. Amphetamine is representative of a broader group of compounds with a shared structure known as phenylethylamines, which is a more precise term. Numerous substitutions are possible on the phenylethylamine structure, resulting in a variety of compounds, some with unique properties. For the purposes of this chapter, all phenylethylamines that are not actually amphetamine will be called amphetamines, and the name amphetamine specifically refers to β -phenylisopropylamine.

Amphetamine was first synthesized in 1887, but was essentially lost until the 1920s, when there were concerns about the supply of ephedrine for asthma therapy.⁷¹ The attempt to synthesize ephedrine led to the rediscovery of dextroamphetamine in the United States and methamphetamine (d-phenylisopropylmethylamine hydrochloride) in Japan.⁷¹ Amphetamine was first marketed by Smith, Kline, and French in 1932 as the nasal decongestant Benzedrine.¹⁵ Amphetamine tablets were later available in 1935 for the treatment of narcolepsy and were advocated as anorectants in 1938.⁷⁶

Both amphetamine and methamphetamine were supplied as stimulants for soldiers and prisoners of war in World War II. The stimulant and euphoric effects of amphetamine were recognized, with abuse reported as early as 1936.¹³⁷ As a result, Benzedrine inhalers were banned by the US Food and Drug Administration (FDA) in 1959. From 1950 to the 1970s, there were sporadic periods of widespread amphetamine use and abuse in the United States. In the 1960s, various amphetamines such as methylenedioxyamphetamine (MDA), para-methoxyamphetamine (PMA), and para-methoxymethamphetamine (PMMA) were popularized as hallucinogens.³⁴ The Controlled Substance Act of 1970 placed amphetamines in Schedule II to prevent the diversion of pharmaceutical amphetamines for nonmedicinal uses.⁵ Amphetamine abuse subsequently declined.⁹³

In the 1980s, use of methylenedioxy derivatives of amphetamine and methamphetamine surfaced and were able to circumvent existing regulations. The best known of these derivatives were 3,4-methylenedioxymethamphetamine (MDMA) and 3,4-methylenedioxyethamphetamine (MDEA).⁴⁶ Since the late 1980s, a dramatic resurgence of methamphetamine abuse has spread throughout much of the United States. A high purity preparation of methamphetamine hydrochloride was marketed in a large crystalline form termed “ice” by abusers.^{7,49} From 1991 to 1994, the number of methamphetamine-related deaths in the United States reported by medical examiners tripled from 151 to 433, with a disproportional distribution from the Los Angeles, San Diego, San Francisco, and Phoenix metropolitan areas. Methamphetamine use is particularly prevalent among men who have sex with men in New York City.⁷⁴ Because of the ease and low cost of methamphetamine synthesis and the local production, methamphetamine is the most common illicit drug produced by

clandestine laboratories in the United States.^{28,31} Since the mid-1990s, MDMA has become widely used by college students and teenagers in large gatherings, known as “rave” or “techno” parties in England, Australia, and the United States.^{135,136} Methcathinone (a khat-derived substance) use in the midwestern United States and 4-bromo-2,5-methoxyphenylethylamine (2CB) use in dance clubs were popular in the 1990s, but the use was not widespread.^{63,67,180} Recently, synthetic cathinones have resulted in serious toxicity and death³⁰; these drugs have been sold as “bath salts” or “legal highs” to circumvent existing laws. There are also older amphetamines such as PMA and PMMA that have made a resurgence, with recent reports of toxicity and deaths.

PHARMACOLOGY

The pharmacologic effects of amphetamines are complex, but their primary mechanism of action is the release of catecholamines, particularly dopamine, norepinephrine, and serotonin from the presynaptic terminals, leading to a hyperadrenergic state. Although there are conflicting mechanistic models of amphetamine induction of catecholamine release, these variable results may be directly correlated with the different concentrations of amphetamine used in experimental models. The mechanism of action of amphetamines are based on dopaminergic neurons; similar mechanisms occur with norepinephrine and serotonin. Two storage pools exist for dopamine in the presynaptic terminals: the vesicular pool and the cytoplasmic pool. The vesicular storage of dopamine and other biogenic amines is maintained by the acidic environment within the vesicles and the persistence of a stabilizing electrical gradient within the cytoplasm. This environment is maintained by an adenosine triphosphate (ATP)-dependent active proton transport system.^{117,147}

Amphetamines will enter the nerve cell either by passive diffusion or by exchange diffusion through a reuptake transporter that is partially dose dependent. At low concentrations, amphetamines release dopamine from the cytoplasmic pool by exchange diffusion at the dopamine reuptake transporter site in the membrane. At moderate concentrations, amphetamines diffuse through the presynaptic terminal membrane and interact with the neurotransmitter transporter on the vesicular membrane to cause exchange release of dopamine into the cytoplasm. Dopamine is subsequently released into the synapse by reverse transport at the dopamine reuptake site.^{147,161} At high concentrations, an additional mechanism is invoked as amphetamines diffuse through the cellular and vesicular membranes. Because amphetamine are bases, they alkalize the vesicles, permitting dopamine release from the vesicles and delivery into the synapse by reverse transport (Fig. 76–1).^{161,162} Amphetamines may also block the reuptake of catecholamines by competitive inhibition.^{72,177} However, the effects of this mechanism are considered minor. Amphetamines are structurally similar to amphetamine derived monoamine oxidase inhibitors such as tranylcypromine, so amphetamines are weak monoamine oxidase inhibitors, the clinical significance of which is unclear.¹³¹

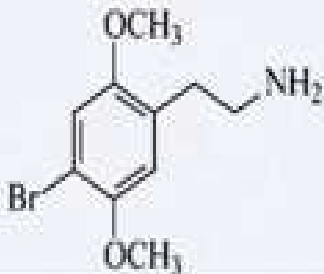

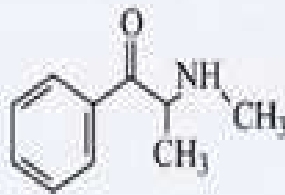

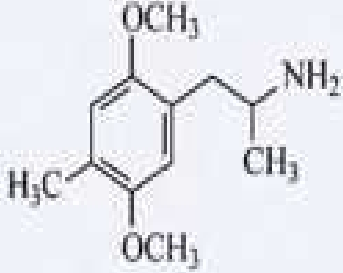

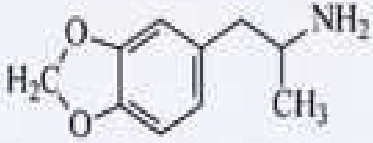

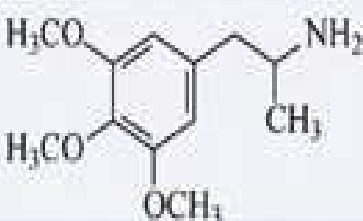

FIGURE 76–1. Noradrenergic nerve ending. The postsynaptic membrane may represent an end organ or another neuron in the CNS. The primary mechanism of action of amphetamines is the release of catecholamines, particularly dopamine and norepinephrine, from the presynaptic terminals. Two storage pools exist for dopamine in the presynaptic terminals: the vesicular pool and the cytoplasmic pool. The vesicular storage of dopamine and other biogenic amines is maintained by the acidic environment within the vesicles and the persistence of a stabilizing electrical gradient with respect to the cytoplasm. [1,2] Activating or antagonizing postsynaptic α - and β -adrenoceptors. [3] Amphetamines release dopamine from the cytoplasmic pool by exchange diffusion at the dopamine uptake transporter site in the membrane. [4] Amphetamines diffuse through the presynaptic terminal membrane and interact with the neurotransmitter transporter on the vesicular membrane to cause exchange release of dopamine into the cytoplasm. Dopamine is subsequently released into the synapse by reverse transport at the dopamine uptake site. [5] Amphetamine diffuses through the cellular and vesicular membranes, alkalinizing the vesicles, and permitting dopamine release from the vesicles and delivery into the synapse by reverse transport. [6] Inhibiting monoamine oxidase (MAO) to prevent NE degradation; or inhibiting COMT to prevent NE degradation. AADC = aromatic L-amino acid decarboxylase; β -hydroxylase = dopamine- β -hydroxylase; COMT = catechol-O-methyltransferase; CNS = central nervous system; DOPGAL = 3,4-dihydroxyphenylglycoaldehyde; G = G protein; NET = membrane NE uptake transporter; NME = normetanephrine; VMA2 = vesicle uptake transporter for NE; PNS = peripheral nervous system.

Binding selectivity to the neurotransmitter transporters largely determines the range of pharmacologic effects for the particular amphetamine. The affinity of MDMA for serotonin transporters is 10 times greater than that for dopamine and norepinephrine transporters; hence, it produces primarily serotonergic effects.⁶⁸ There are also other amphetamines that are predominantly serotonergic such as paramethoxyamphetamine and BromodragonFLY (Table 76–1).

TABLE 76–1. Examples of Amphetamines

<i>Xenobiotic</i>	<i>Clinical Manifestations</i>	<i>Structure</i>
4-Bromo-2,5-dimethoxyamphetamine (DOB)	Marked psychoactive effect, potency > mescaline Delayed onset of action, peak 3–4 hours Fantasy, mood altering for 10 hours, resolution 12–24 hours Agitation, sympathetic excess Sold as impregnated paper, like LSD	
4-Bromo-2,5-methoxyphenyl-ethylamine (2CB, MFT)	Relaxation Sensory distortion Agitation Hallucination Potency > mescaline	
Methcathinone (cat, Jeff, Khat, ephedrone)	Hallucinations Sympathetic excess	
4-Methyl-2,5-dimethoxyamphetamine (DOM/STP) (serenity, tranquility, peace)	Narrow therapeutic index Euphoria, perceptual distortion Hallucinations, sympathetic excess	
3,4-Methylenedioxyamphetamine (MDA, love drug)	Empathy, euphoria Agitation, delirium, hallucinations, death associated with sympathetic excess	
3,4-Methylenedioxyethamphetamine (MDEA, Eve)	Comparable to MDMA Sympathetic excess	
3,4-Methylenedioxymethamphetamine (MDMA, Adam, molly, ecstasy, XTC)	Psychotherapy "facilitator" Euphoria, empathy, nausea, anorexia, anxiety, insomnia Sympathetic excess	
para-Methoxyamphetamine (PMA)	Potent hallucinogen Sympathetic excess	
2,4,5-Trimethoxyamphetamine	Similar to mescaline	

The most identifiable effects of amphetamines are those caused by excessive catecholamine release and the resultant stimulation of many receptors that include α -adrenergic receptors, β -adrenergic receptors, dopamine, and serotonin. The majority of the serotonergic neurons in the central nervous system (CNS) are located in the raphe nuclei. Serotonin within the CNS regulate a wide variety of functions, including, but not limited to, mood, memory, temperature regulation, sleep, and pain.⁷¹ Serotonin is primarily responsible for the hallucinogenic and illusionic properties of amphetamines. Serotonin is also involved with the release of antidiuretic hormone, which may lead to hyponatremia, particularly with amphetamines with potent serotonergic effects such as MDMA.⁷⁵ Serotonin is also concerned with regulating fluid secretion and peristalsis. In addition, serotonin is involved in the regulation of many vascular beds, although the role of amphetamines in the regulation of the peripheral effects of serotonin is not clear.

Norepinephrine is another important neurotransmitter involved with amphetamines. Norepinephrine is found in the CNS and is also released from the postganglionic sympathetic fibers. The main noradrenergic nucleus in the CNS is the locus ceruleus. The release of excessive norepinephrine within the CNS from amphetamines results in decreased fatigue and increased attentiveness. Excessive norepinephrine in the peripheral nervous systems leads to many of the findings that occur with other sympathomimetic drugs such as cocaine. Norepinephrine will act on the adrenergic receptors (α and β), which mediate vasoconstriction and increased cardiac activity resulting in hypertension and tachycardia.

Dopamine also plays an important role in the setting of amphetamine use. The increase in CNS dopamine, particularly in the neostriatum, mediates stereotypical behavior and other locomotor activities.^{39,65,89,90} The activity of dopamine in the neostriatum appears to be linked to glutamate release and inhibition of γ -aminobutyric acid (GABA) ergic efferent neurons.^{65,90} Stimulation of the glutamatergic system contributes significantly to the stereotypical behavior, locomotor activity, and neurotoxicity of amphetamines.^{90,153,154} The effects of serotonin and dopamine on the mesolimbic system alter perception, cause psychotic behavior and anorexia.^{78,160}

Structure Modification

A phenylethylamine is any structure with an ethyl group backbone that has an aromatic group and a terminal amine. Specific substitutions made to the phenylethylamine backbone have led to the wide variety of novel drugs, described below. Substitutions at different positions of the phenylethylamine molecule alter the general pharmacology and clinical effects of amphetamines, as demonstrated by both animal and human observations. Large-group substitution at the α carbon reduces the stimulant and cardiovascular effects but retains the anorectic properties (such as phentermine). Substitution at the para position of the phenyl ring enhances the hallucinogenic or serotonergic effects of amphetamines (such as in para-chloroamphetamine and MDMA).⁴⁹ Although some of these generalizations enable an understanding of the effects of amphetamines, there are many exceptions, and such generalizations may not apply when large doses of a particular molecule are ingested. In terms of the spectrum of activities, methamphetamine results in the most potent cardiovascular effects, and 2,5-dimethoxy-4-bromoamphetamine (DOB) results in the most consequential hallucinogenic and serotonergic effects.¹⁰⁵ Table 76–2 further describes the pharmacology of specific substitutions.

TABLE 76–2. Specific Substitutions

<i>Substitution</i>	<i>Pharmacological Effect</i>
α -Carbon	Indirect acting Resists oxidation by monoamine oxidase
β -Carbon	Decreases central nervous system penetration Hydroxyl ($-\text{OH}$): necessary for adrenergic activity
Amino group	No substitution: α -adrenergic > β -adrenergic effects Larger group: β -adrenergic > α -adrenergic effects t-butyl group: β_2 -adrenergic selective Methyl ($-\text{CH}_3$) group: maximum α - and β -adrenergic effects
3-, 4- of aromatic ring	Hydroxylation at 3- and 4-: increased α - and β -adrenergic effects Absence of hydroxylation (at one or both positions) prevents degradation by catechol-O-methyltransferase
Halogenation	Increases neurotoxic properties of amphetamines by selective action on the serotonin system Enhances potency

Other certain substitutions are worth noting, such as the addition of an extra methyl group to the terminal amine in amphetamine to produce methamphetamine that greatly increases CNS activity. This extra methyl group also makes methamphetamine more lipid soluble, allowing faster penetration across the blood–brain barrier and more resistance to degradation by monoamine oxidase. In addition, amphetamines with this methyl group also possess strong stimulant, cardiovascular, and anorectic properties.¹⁰⁵ Addition of a methoxy group to either the 2 or 5 position of the aromatic ring on the amphetamine or methamphetamine compound increases serotonergic activity. Another important substitution to the phenylethylamine backbone is the addition of a halogen group (such as iodine or bromide), which increases the potency of the compound and leads to it being considered more neurotoxic when compared to nonhalogenated compounds. This is thought to be due to significant serotonin depletion leading to irreversible neuron damage.

Because amphetamines directly interact with neurotransmitter transporters, minor modifications of the molecule may significantly alter its pharmacologic profile.⁸² The addition of an α -methyl group in amphetamines confers resistance to metabolism by monoamine oxidase. These characteristics permit better oral bioavailability and longer duration of effect. The α -methyl group in the amphetamine structure also introduces chirality to the molecule. Except for MDMA and several other amphetamines, the d-enantiomers are typically 4 to 10 times more potent than the l forms of amphetamine.

Chronic administration of certain amphetamines to animals alters dopamine and serotonin transporter functions, depletes dopamine and serotonin in the neuronal synapses, and produces irreversible destruction of those neurons.^{14,60,141,142,147,176} The etiology of neuronal toxicity may be related to the generation of oxygen free radicals, resulting in the generation of toxic dopamine and serotonin metabolites as well as neuronal destruction. Based on animal models, dose, frequency and duration of exposure, and ambient temperature. Intact dopamine or serotonin transporters are necessary to produce neurologic injury. Xenobiotics that inhibit transporter function may prevent neurologic injuries in animals.⁶⁸ Significant differences are also noted across species; mice are typically resistant to MDMA-induced neurologic injury. Although not as well studied as MDMA, studies of former methamphetamine users demonstrated impaired memory and psychomotor functions, as well as corresponding dopamine transporter dysfunction and abnormal glucose metabolism on positron emission tomography scans. However, it is still not clear as to the difference in species susceptibility to neurologic injuries, the duration of effects in primates and humans, and functional consequences of neurotoxicity in humans. The potential for permanent neurologic effects associated with chronic amphetamine use in humans requires further study.

PHARMACOKINETICS AND TOXICOKINETICS

Absorption

Amphetamines can be administered intravenously, orally, intranasally, and by inhalational route, with good absorption. All amphetamines are rapidly absorbed, with bioavailability that ranges between 60% and 90% depending on the route of administration. Peak serum concentrations are achieved in approximately 3 to 6 hours postadministration.

Distribution

Following absorption, amphetamines are distributed to most compartments of the body. Most amphetamines are also relatively lipophilic and readily cross the blood–brain barrier. Amphetamines have large volumes of distribution, varying from 3 to 5 L/kg for amphetamine, 3 to 4 L/kg for methamphetamine and phentermine, and to 11 to 33 L/kg for methylphenidate. Some amphetamines such as pemoline have a small volume of distribution (0.2–0.6 L/kg).

Metabolism

Amphetamines are eliminated via multiple pathways, including diverse routes of hepatic transformations, and by renal elimination. For MDMA and its analogs, N-dealkylation, hydroxylation, and demethylation are the dominant hepatic pathways. Depending on the particular amphetamines, active metabolites of amphetamines and ephedrine derivatives may be formed. N-demethylation of methamphetamine and MDMA result in the formation of amphetamine and MDA, respectively.^{33,111} Dealkylation and demethylation are mainly performed by CYP1A2, CYP2D6, and CYP3A4, but they are also performed by flavin monooxygenase. Polymorphism of CYP2D6 in humans was recognized due to the diversity of rates of p-hydroxylation of amphetamines. Since its discovery, CYP2D6 polymorphism has been implicated in drug toxicity, substance use and abuse, and lack of drug efficacy in selected individuals.¹⁴⁸ Increased amphetamine toxicity is a potential concern in patients with decreased CYP2D6 activity. Although animals with CYP2D6 deficiency are more susceptible to MDMA toxicity, limited studies in humans do not demonstrate an association between mortality and CYP2D6 polymorphism.^{59,122} In general, because multiple enzymes and pathways (including renal) are involved in amphetamine metabolism, it is less likely that CYP2D6 polymorphism or drug interactions with CYP3A4 alone will significantly increase toxicity. However, it is unclear if toxicity is enhanced when multiple mechanisms for altering drug metabolism and kidney dysfunction are present simultaneously.

Elimination

Renal elimination of the parent compound is substantial for amphetamine (30%), methamphetamine (40%–50%), MDMA (65%), and phentermine (80%). Amphetamines are bases with a typical pK_a range of 9 to 10, and renal elimination varies depending on the urine pH, with elimination increasing as pH decreases. The half-life of amphetamines varies significantly: amphetamine, 8 to 30 hours; methamphetamine, 12 to 34 hours; MDMA, 5 to 10 hours; methylphenidate, 2.5 to 4 hours; and phentermine, 19 to 24 hours. Repetitive administration, which occurs typically during binge use, may lead to drug accumulation and prolongation of the apparent half-life and duration of effect.⁷⁷

CLINICAL MANIFESTATIONS

Acute Toxicity

Most of the complications associated with amphetamines are a result of an uncontrolled hyperadrenergic state similar to what occurs with other sympathomimetics such as cocaine, except the duration of effect may be longer (Table 76–3). Most patients with acute amphetamine toxicity manifest effects in the CNS and cardiovascular system. The majority of the specific effects are from excessive catecholamine release as opposed to direct effects from the amphetamines themselves. Refer to the section Individual Amphetamines for specific effects.

TABLE 76–3. Clinical Manifestations of Amphetamine Toxicity

Acute

Cardiovascular system

Aortic dissection

Dysrhythmias

Hypertension

Myocardial ischemia

Tachycardia

Vasospasm

Central nervous system

Agitation

Anorexia

Bruxism

Choreoathetoid movements

Euphoria

Headache

Hyperreflexia

Hyperthermia

Intracerebral hemorrhage

Paranoid psychosis

Seizures

Other sympathomimetic symptoms

Diaphoresis

Mydriasis

Nausea

Tachypnea

Tremor

Other organ system manifestations

Acute respiratory distress syndrome

Ischemic colitis

Muscle rigidity

Rhabdomyolysis

Laboratory abnormalities

Creatine phosphokinase elevated

Hyperglycemia

Hyponatremia

Leukocytosis

Liver enzymes elevated

Myoglobinuria

Chronic

Aortic and mitral regurgitation

Cardiomyopathy

Dopaminergic and serotonergic neuron damage

Pulmonary hypertension

Vasculitis

Central nervous system effects from acute amphetamine use include anxiety, agitation, hallucinations, mydriasis, diaphoresis, and hyperthermia.^{19,50,51,145} Psychosis appears to be a more prominent feature than following cocaine use.⁶⁵ Intracerebral hemorrhage and cerebral infarction are also reported with amphetamine use.^{53,86,113,129} Seizures may be the direct result of amphetamine use or may occur secondarily from hyponatremia as reported with MDMA and certain synthetic cathinones.¹⁸

Cardiovascular toxicity from acute amphetamine use involves hypertension, tachycardia, and dysrhythmias; this varies from premature ventricular complexes to ventricular tachycardia and ventricular fibrillation.⁸⁰ Other vascular complications reported with acute use include myocardial ischemia or infarction,^{115,169} aortic dissection,^{52,172} acute respiratory distress syndrome,^{165,171} obstetrical complications, fetal death,¹⁰⁴ and ischemic colitis.^{79,84} Other complications are metabolic acidosis, rhabdomyolysis,⁵⁴ acute kidney injury (acute tubular necrosis), and coagulopathy, often from uncontrolled agitation and hyperthermia^{43,73,167} (Fig. 5–29). Unless these systemic signs and symptoms are rapidly reversed, multiorgan failure and death may ensue.

Chronic Toxicity

Amphetamine users seeking intense “highs” may go on “speed runs” for days to weeks. Because of the development of tolerance, they use increasing amounts of amphetamine during these periods, usually without much nutritional sustenance or sleep, while attempting to achieve their desired euphoria.¹⁵¹ Acute psychosis resembling paranoid schizophrenia may occur during these binges and has contributed to both amphetamine-related suicides and homicides.⁵⁵ Return to a normal sensorium occurs within a few days after discontinuation of the drug. Once an amphetamine user experiences psychosis, it is likely to recur with subsequent use, even after prolonged abstinence, which may be related to a kindling phenomenon.¹¹⁴ Typically, after such binges, patients may sleep for prolonged periods of time, feel hungry and depressed when awake, and often have amphetamine cravings.^{95,99}

Compulsive repetitive behavior patterns from the use of amphetamines are reported in humans and animals. Individuals may constantly pick at their skin; grind their teeth (bruxism); or perform repetitive tasks, such as constantly cleaning the house or car. MDMA users often carry pacifiers to relieve bruxism. Choreoathetoid movements, although uncommon, are reported with acute and chronic amphetamine usage.^{94,106,110} The etiology of the choreoathetoid movements may be related to increased dopaminergic stimulation in the striatal area.

Necrotizing vasculitis is associated with amphetamine abuse. Angiography typically demonstrates beading and narrowing of the small- and medium-sized arteries (Fig. 5–29). Progressive necrotizing arteritis can involve multiple organ systems, including the brain, heart, gut, and kidney.^{17,35,98,110,164} Complications include cerebral infarction and hemorrhage, coronary artery disease, pancreatitis, and acute kidney injury. The etiology of the arteritis remains unclear. Although various contaminants associated with injection drug use are postulated as potential etiologies, in animal models oral and intravenous amphetamine administration is also associated with vasculitis, suggesting that this is a direct amphetamine effect. Cardiomyopathy is also reported with acute and chronic amphetamine abuse.^{157,178} Excessive catecholamine exposure may be responsible for their associated cardiomyopathies similar to patients with pheochromocytomas and chronic cocaine use.^{88,173} Other reported effects include valvular disease and pulmonary hypertension with certain amphetamines used as dieting agents such as fenfluramine, dexfenfluramine, and phentermine.^{146,163}

Finally, complications can result from intravenous drug use and from the associated contaminants. Contamination with microbials may lead to human immunodeficiency virus infection, hepatitis, and malaria. Bacterial and foreign body contamination may result in endocarditis, tetanus, wound botulism, osteomyelitis, and pulmonary and soft tissue abscesses.³⁴

DIAGNOSTIC TESTING

The choice and extent of diagnostic tests should be guided by the history and physical examination. In all patients with altered mental status, blood specimens should be sent for glucose, blood urea nitrogen, and electrolyte assays. An electrocardiogram should be obtained in all cases, and continuous cardiac monitoring should be initiated. A complete blood count, urinalysis, coagulation profile, creatine phosphokinase, chest radiograph, computed tomography scan of the head, and lumbar puncture may be necessary, depending on the clinical presentation.

Qualitative urine immunoassays are available for amphetamines, but several considerations limit their utility in the

management of acutely poisoned patients. While point of care urine tests are available, the turnaround time for many urine immunoassays is at least several hours so they rarely contribute to management in the acute setting. Another important limitation to consider is the rate of false-positive and false-negative results that are common with the amphetamine immunoassay. For example, many cold preparations contain pseudoephedrine, which is structurally similar and may cross-react with the immunoassay.^{36,41,57,132} Likewise, selegiline, a selective monoamine oxidase type B inhibitor used for the treatment of parkinsonism, is metabolized to amphetamine and methamphetamine. Other common drugs that produce false-positive outcomes include bupropion, trazodone, and amantadine.^{120,124} Even a true-positive result only means the patient has used certain amphetamines within the past several days and does not distinguish remote from acute use. False-negative results may occur with certain amphetamines such as MDMA and cathinones, which are not recognized on standard urinary drug testing.^{36,156} Although newer, rapid, serum qualitative drug screens are available, false-positive and false-negative results remain common and may be misleading and do not directly contribute to the acute management of patients. The gold standard for drug testing, gas chromatography–mass spectrometry analysis, can misidentify isomeric substances such as l-methamphetamine, which is present in nasal inhalers, with d-methamphetamine, if performed by inexperienced personnel.⁹⁶ In summary, the use of urine immunoassays should not guide clinical management of patients who present with suspected toxicity from amphetamines.

MANAGEMENT

The initial medical assessment of the agitated patient must include vital signs, a rapid glucose and a complete physical examination. Determination of core body temperature is essential to diagnose the presence and degree of hyperthermia, which is a frequent and rapidly fatal manifestation in patients with drug-induced delirium. Significant hyperthermia necessitates immediate interventions to achieve rapid cooling.^{16,23,62} Some patients require temporary physical restraint to gain pharmacologic control and prevent personal harm to themselves or others. Physical restraints should be discontinued as soon as possible; prolonged restraints may result in rhabdomyolysis and continued heat generation. Intravenous access should be obtained so that intravenous sedation can be initiated. In the event that intravenous access cannot be obtained, it is necessary to attempt to administer intramuscular benzodiazepines such as midazolam until definitive access is made.

The most appropriate choice of chemical sedation is a benzodiazepine because of the characteristic high therapeutic index, good anticonvulsant activity, and predictable pharmacokinetic properties. The benzodiazepines are effective not only for the treatment of delirium induced by acute overdose of cocaine, amphetamines, and other xenobiotics but also the delirium associated with ethanol and sedative-hypnotic withdrawal (Antidotes in Depth: A23).^{47,48,66,123} Sedation should be titrated rapidly until the patient is calm. In our clinical experience, cumulative benzodiazepine dosages required in the initial 30 minutes to achieve adequate sedation frequently exceed 100 mg of diazepam or its equivalent. Intravenous glucose (D₅₀W, 0.5–1 g/kg) and thiamine 100 mg should be given as indicated (Table 76–4).

TABLE 76–4. Management of Patients with Amphetamine Toxicity

Agitation

Benzodiazepines (usually adequate for the cardiovascular manifestations)

Diazepam 10 mg (or equivalent) intravenously, repeat rapidly until the patient is calm (cumulative dose may be as high as 100 mg of diazepam). An equivalent dose of intramuscular midazolam can be used if intravenous access is not available.

Seizures

Benzodiazepines

Barbiturates

Propofol for status epilepticus (typically will require endotracheal intubation)

Hyperthermia

External cooling

Control agitation rapidly

Gastric decontamination and elimination

Activated charcoal for recent ingestions

Hypertension

Control agitation first

α -Adrenergic antagonist (phentolamine)^a

Vasodilators (nitroprusside, nitroglycerin, or possibly nicardipine)

Delirium or hallucinations with abnormal vital signs

If agitated: benzodiazepines

^aAvoid β -adrenergic antagonists, especially with suspected cocaine toxicity.

Antipsychotics, particularly potent dopamine antagonists such as haloperidol and droperidol, are frequently recommended by others for amphetamine-induced delirium. Antipsychotics may antagonize some of the effects of amphetamines via dopamine blockade, but they have not been shown to be as effective as benzodiazepines in experimental models.^{44,66,123} Additionally, antipsychotics may lower the seizure threshold, alter temperature regulation, cause acute dystonia, and precipitate cardiac dysrhythmias, and they do not interact with the benzodiazepine-GABA-chloride channel receptor complex. All of these effects may aggravate the clinical outcomes related to occult or concomitant cocaine toxicity and ethanol withdrawal.^{66,69,123} Based on these concerns, benzodiazepines should be utilized as first-line treatments in the management of acute toxicity from amphetamines.

Rhabdomyolysis from amphetamines usually results from psychomotor agitation and hyperthermia.¹⁴³ Sedation prevents further muscle contraction and heat production. External cooling should be instituted for hyperthermia. Adequate intravenous hydration and cardiovascular support should maintain urine output of at least 1 to 2 mL/kg/h. Although urinary acidification can significantly increase amphetamine elimination and decrease the half-lives of amphetamine and methamphetamine,^{11,12} pH manipulation does not decrease toxicity, and, in fact, it may increase the risk of acute kidney injury from rhabdomyolysis by precipitating ferrihemate in the renal tubules.⁴⁰ Patients with acute kidney injury, acidemia, and hyperkalemia may require urgent hemodialysis.

Amphetamine body packers, although uncommon, should be treated similarly to those who transport cocaine (Special Considerations: SC5). Any sympathomimetic symptom suggesting leakage of the packets requires surgical intervention.¹⁶⁸ Intravenous fluids, benzodiazepines, intubation, and external cooling may be necessary to stabilize these patients.

INDIVIDUAL AMPHETAMINES

Methamphetamine

Methamphetamine is known by many names, including, but not limited to, “yaba,” “speed,” “go,” “crack,” “uppers,” and “dexies.” The terms “crystal,” “shard,” and “ice” refer to the crystalline form of methamphetamine. Methamphetamine was first synthesized from ephedrine in Japan in 1893, soon after the synthesis of amphetamine in 1887. Crystallized

methamphetamine was synthesized in 1919 through the reduction of ephedrine using red phosphorus. From the 1950s to the 1970s, there were multiple epidemics of methamphetamine abuse in the United States.⁶⁴ Methamphetamine is approved by the FDA for the short-term treatment of attention-deficit/hyperactivity disorder and obesity, and it is sold under the trade name Desoxyn as a Schedule II drug. It is also prescribed for off-label use for refractory depression and narcolepsy.

The production of methamphetamine is relatively simple, requiring minimal equipment and chemicals. There are many methods of methamphetamine production which initially utilize pseudoephedrine, ephedrine, or phenyl-2-propone (P2P). The primary ingredient of methamphetamine synthesis is ephedrine, which can be hydrogenated into methamphetamine. The ephedrine method, using pharmaceutical grade L-ephedrine, produces a product with few contaminants that is stereochemically pure.^{49,133} P2P, as an alternative ingredient, can be methylated into ephedrine and then transformed into methamphetamine.²² Because of the strict control of ephedrine and P2P, illicit chemists use phenylacetic acid to synthesize P2P.^{22,42} Lead acetate, which is used as a substrate for the reaction, has resulted in an epidemic of lead poisoning associated with methamphetamine abuse in Oregon.^{2,121} Mercury contamination was also documented, although clinical mercury toxicity has not been reported.²⁰ Methamphetamine laboratories use many xenobiotics, including phosphine gas, methylamine gas, chloroform, and hydrochloric acid^{3,81}; therefore, these laboratories pose a significant health risk to law enforcement officers and the general public, causing respiratory and ophthalmic irritation, headaches, and burns.^{28,155} Currently, the sale of other potential amphetamine synthetic ingredients, such as hydrochloric acid, hydrogen chloride gas, anhydrous ammonia, red phosphorus, and iodine, are also monitored and restricted in the United States.^{22,29}

Methamphetamine exists as a chiral molecule with two isomers that include levomethamphetamine and dextromethamphetamine. Although the levorotatory form is devoid of CNS stimulatory properties, it retains its vasoactive effects and is used in nonprescription nasal decongestant inhalers. In the racemic mixture, the dextrorotatory form is responsible for the entire stimulant effects observed with methamphetamines. Methamphetamine undergoes metabolism in the liver mainly to amphetamine and 4-hydroxymethamphetamine and has prolonged half-life of 19 to 34 hours, although the duration of its acute effects can be greater than 24 hours.⁴⁹

3,4-Methylenedioxymethamphetamine (MDMA)

3,4-Methylenedioxymethamphetamine, also known as MDMA, was first synthesized in 1912, and was rediscovered in 1965 by Shulgin. MDMA is known as “ecstasy,” “E,” “Adam,” “XTC,” “molly,” and “MDM,” and it is commonly abused by college students and teenagers.^{128,170,174} Other amphetamines that are similar to MDMA, include MDEA (“Eve”) and MDA (“love drug”), which have similar clinical effects, are also used or distributed as MDMA in areas of MDMA use. Amphetamines sold as MDMA include 2CB, 2,4-dimethoxy-4-(n)-propylthiophenylethylamine (2C-T7), and N-methyl-1-(3, 4-methylenedioxyphenyl)-2-butanamine (MBDB).^{27,63,92} The term “ecstasy” may be used for all these xenobiotics. Typically, MDMA is available in 50 to 200 mg colorful and branded tablets.

MDMA and similar analogs are so-called entactogens (meaning touching within), capable of producing euphoria, inner peace, and a desire to socialize.¹⁵² In addition, some psychologists used MDMA to enhance psychotherapy until the Controlled Substances Act of 1986 placed MDMA in Schedule I, thereby eliminating its medical use.¹¹⁹ People who use MDMA report that it enhances pleasure, heightens sexuality, and expands consciousness without the loss of control.⁷⁰ Negative effects reported with acute use included ataxia, restlessness, confusion, poor concentration, and impaired memory.¹⁵² MDMA has about one-tenth the CNS stimulant effect of amphetamine. Unlike amphetamine and methamphetamine, MDMA is a potent stimulus for the release of serotonin.^{24,45,72} The concentration of MDMA required to stimulate the release of serotonin is 10 times less than that required for the release of dopamine or norepinephrine. In animal models, the stereotypic and discriminatory effects of MDMA and its congeners can be distinguished from those of other amphetamines.²⁴

The sympathetic effects of MDMA are mild in low doses. However, when a large amount of MDMA is taken, the clinical presentation is similar to that of other amphetamines, and deaths can result from abuse.^{61,91,138} Those patients at greatest risk develop dysrhythmias, hyperthermia, rhabdomyolysis, and disseminated intravascular coagulation.¹³⁸ Significant hyponatremia is reported with MDMA use.^{1,21,75} MDMA and its metabolites increase the release of vasopressin

(antidiuretic hormone), and this may be related to the serotonergic effects.⁵⁶ Furthermore, substantial free water intake combined with sodium loss from physical exertion in dance clubs may exacerbate the development of hyponatremia.

Most recently, reports of poisoning from a form of MDMA known as Molly have emerged. Molly is initially thought to be a purified or crystallized form of MDMA that is typically taken orally. Molly use has increased due to what was perceived as a more rapid onset of symptoms and a subtler offset or “come down” period. Molly is also commonly viewed as a safer form of MDMA, since it is believed to contain no adulterants. The use of Molly is associated with adverse effects such as intracranial hemorrhage.⁸⁵ While Molly is often sold on the street as MDMA, Molly may not be pure MDMA but actually may contain 2C compounds, amphetamines that have two methoxy groups and a halogen such as iodine (2C-I) or bromide (2C-B). The compound 2C-I is known as “smiles.”

A major concern with MDMA use is its long-term effects on the brain. In numerous animal models, acute administration of MDMA leads to the decrease in serotonin reuptake transporter (SERT) function and number. Recovery of SERT function may take several weeks. Repetitive administration of MDMA ultimately results in permanent damage to serotonergic neurons, typically causing injury to the axons and the terminals while sparing the cell bodies.^{112,140,141} Some regeneration of synaptic terminals can occur even with neuronal damage, but functional recovery is incomplete. Intact SERT function is necessary for MDMA-induced neurotoxicity. Xenobiotics that inhibit the reuptake of serotonin prevent MDMA-induced neurotoxicity in animals. Animal data suggest that MDMA induces hydroxyl free-radical generation and decreases antioxidants in serotonergic neurons.¹⁴⁹ MDMA itself is not the ultimate neurotoxin, rather its metabolites 3-methyldopamine and N-methyl- α -methyldopamine appear to be responsible in animals.¹¹⁶ When antioxidants are depleted, neuronal damage may occur.

Paramethoxyamphetamine (PMA) and Paramethoxymethamphetamine (PMMA)-Monomethoxy Derivatives

Para-methoxyamphetamine (PMA) is the 4-methoxylated analog of amphetamine, and para-methoxy-N-methylamphetamine (PMMA; methyl-MA) is the 4-methoxy analog of methamphetamine. PMA was first produced in 1973 and sold as a hallucinogen for a short period of time, and it reemerged in the 1990s. PMMA soon appeared after PMA, with multiple reports of death also emerging during that time.^{10,83,97,102} PMA and PMMA are commonly found as tablets or capsules sold as MDMA or “ecstasy.” While the effects of PMA and PMMA mimic some aspect of MDMA and methamphetamine, there are unique properties of PMA and PMMA, that make them considerably more lethal and earning the street name “death.” In recent years, there have been more than 100 fatalities and severe poisonings attributed to PMMA and PMA in the United States, Canada, and Europe.^{87,100,103,107,109}

Methoxy ring substitution of amphetamine or methamphetamine at the 3 or 4 positions (para substitution is the most common) yields PMA and PMMA derivatives that have significantly less sympathomimetic activity than amphetamine but very potent serotonergic activity.^{38,158} Both PMA and PMMA inhibit reuptake of serotonin and inhibit monoamine oxidase A found centrally and peripherally. The methoxy ring substitution is also responsible for poor penetration of the blood brain barrier.^{6,58}

PMA and PMMA poisoning lead to autonomic hyperactivity similar to what is observed in other amphetamines such as hypertension, tachycardia, and agitation. The use of PMA and PMMA results in a weak euphoric effect and delayed onset of CNS effects due to poor blood–brain barrier penetration. These properties will often lead users to repeatedly dose themselves that result in serious toxicity and are responsible for the seemingly high mortality rate.

Cathinones (Methcathinone, MDPV, and Mephedrone)—“Bath Salts”

Cathinone ((S)-2-amino-1-phenyl-1-propanone) is a naturally occurring substance found in the leaves of the *Catha edulis* (khat) plant. Also known as guat and gat, the fresh leaves and stems are commonly used as a stimulant in Africa and certain Middle Eastern countries such as Yemen. While there are numerous other amphetamines in minute quantities, the primary active ingredient is cathinone. As the leaves age, cathinone is degraded to cathine, which has about one-tenth the stimulant effect of D-amphetamine. Imported fresh khat must be consumed within a week, before it loses much of its potency. The primary effects of khat are increased alertness, insomnia, euphoria, anxiety, and hyperactivity. Khat chewing is linked to cardiac and gastrointestinal disease.^{125,126}

The syntheses of cathinone derivatives were reported in the early 1920s, with the production of methcathinone in 1928 and mephedrone in 1929. Methcathinone, the methyl derivative of cathinone, was used in Russia as an antidepressant in the 1930s and 1940s. Also known as “Cat” and “Jeff,” cathinone has been used recreationally, most often in countries formerly part of the Soviet Union, but it also gained popularity in the United States, particularly in Michigan, in the 1990s. Synthetic cathinones have become popular drugs of abuse due to a combination of media attention and widespread Internet availability.^{134,150} Many other synthetic cathinones have been produced including methylone, mephedrone, butylone, methylenedioxypyrovalerone (MDPV), dimethylcathinone, ethcathinone, ethylone, 3- and 4-fluoromethcathinone, and MDPV.

The synthetic cathinones differ from other amphetamines because they contain a ketone at the β position. For this reason, they are often known as β -keto-amphetamines. The β -ketone group is responsible for increased polarity, which decreases penetration of the blood–brain barrier. They possess amphetaminelike properties and have sympathomimetic effects, although as a group, they are considered less potent. Some of the synthetic cathinones are reported to cause hyponatremia. Although the mechanism is not clear and may not be similar to MDMA,^{9,25,26,108,130} Reported complications include compartment syndrome, acute kidney injury, and sudden cardiac death.^{101,118,139,144,179} An irreversible Parkinson syndrome was also described in chronic users of intravenous methcathinone, particularly in Europe and Russia. The methcathinone was manufactured with the use of potassium permanganate to oxidize ephedrine or pseudoephedrine. In one case series, T1-weighted magnetic resonance imaging showed symmetric hyperintensity in the globus pallidus and in the substantia nigra and innominata in all active methcathinone users, suggestive of manganese poisoning, which was also confirmed with elevated whole blood concentrations.¹⁵⁹

Synthetic cathinones are often sold as “bath salts” or “plant food” and labeled as “not for human consumption” in an attempt to circumvent controlled substances legislation. The legal status differs among countries and changes over time. In the United States, the synthetic cathinones were initially unscheduled, but they are illegal for human consumption under the Federal Analogue Act of 1986. However, on September 7, 2011, the Drug Enforcement Administration used its emergency scheduling authority to enact temporary control, making possession or sale of methylenedioxypyrovalerone, methylone, and mephedrone illegal until recently, when permanent law has been enacted.

Bromo-dragonFLY

1-(8-Bromobenzo[1,2-b:4,5-b']difuran-4-yl)-2-aminopropane, also known as Bromo-dragonFLY (BDF), was first synthesized in 1998. BDF was named after its superficial structural resemblance to a dragonfly, similar to earlier and the less potent dihydrofuran series of compounds nicknamed FLY. BDF is a member of a new class of benzodifurans, which have been used as a potent research tools for investigation of the serotonin receptor family and for a time as potential antidepressants.

Structurally, BDF is closely related to other phenylethylamines such as DOB and 2C-B. BDF contains two furan rings on either side of the benzene ring, creating a fully aromatic tricyclic structure. There are a number of similar compounds to

BDF, differing by substitution of the bromide atom with other entities. BDF exists as R- and S-enantiomers, which are both biologically active. The R-enantiomer is considered more potent, with its potent hallucinogenic effect mediated through the 5-HT_{2A} serotonin receptor (also with affinity for the 5-HT_{2B} and 5-HT_{2C} serotonin receptors).¹²⁷

BDF is associated with deaths in Europe and the United States. Reports demonstrate delayed complications from severe peripheral vasoconstriction and limb ischemia that likely result from the potent serotonergic properties of BDF.^{4,37,166,175}

2,5-Dimethoxy-4-Methylamphetamine (DOM) and 2,5-Dimethoxy-4-Iodoamphetamine (DOI)

2,5-Dimethoxy-4-methylamphetamine (DOM), also known as STP, which stands for “Serenity, Tranquility, and Peace,” emerged in the 1960s as a hallucinogen. It was noted for its delayed onset of action and duration of effect that quickly led to its short-lived appearance. 2,5-Dimethoxy-4-iodoamphetamine (DOI) is another potent hallucinogen, previously sold as a substitute for lysergic acid diethylamide, or LSD.

Dimethoxy amphetamine derivatives are structurally characterized by methoxy ring substitution at the 2 and 5 positions on the aromatic ring, with varying additional substitution of hydrophobic moieties at the 4 position. DOM and DOI are both serotonin receptor agonists with selectivity at the 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptor subtypes. Due to this selectivity, DOM and DOI are often used in scientific research involving study of the 5-HT₂ receptor subfamily. DOM exists as a chiral molecule, with the R-(-)-enantiomer considered the more potent.¹³

Potent hallucinogenic effects and dysphoria characterize the use of DOB and DOI, with minimal sympathomimetic effects. These symptoms can often be delayed with a prolonged duration of effect, sometimes refractory to the use of benzodiazepines. There is also report of reversible vasospasm with the use of these dimethoxy amphetamine derivatives.^{8,19}

SUMMARY

- Amphetamines, often created to evade designer drug laws, continue to increase dramatically throughout the United States.
- The extensive knowledge with regard to the modifications to the existing phenylethylamine backbone allows clinicians to predict the effects of the amphetamines. These effects are attributed to variable degrees of selectivity affecting dopamine, norepinephrine and serotonin.
- Many complications associated with amphetamines are similar to those of cocaine, such as agitation, hyperthermia, rhabdomyolysis, myocardial ischemia, and cerebral infarction.
- The management of acute amphetamine toxicity includes supportive care, with the judicious use of benzodiazepines and anticipation of complications of adrenergic toxicity such as hyperthermia and rhabdomyolysis.

77 CANNABINOIDS

Jeff M. Lapoint

HISTORY AND EPIDEMIOLOGY

Cannabis has been used for more than 4000 years. The earliest documentation of the therapeutic use of marijuana is the fourth century B.C. in China.¹⁵⁶ Cannabis use spread from China to India to North Africa, reaching Europe around A.D. 500.¹²⁶ In colonial North America, cannabis was cultivated as a source of fiber. Like cocaine and morphine, cannabis was the focus of research efforts in the 19th century. Although the active chemical constituents of the former were isolated during this time, that of cannabis remained elusive.⁹¹ This is due to the fact that the active compounds of morphine and cocaine are both alkaloids and were possible to extract with the technological means of the time, whereas the methods to isolate the active terpenes in cannabis were not available to researchers until several decades later.

The first pure phytocannabinoid to be isolated was cannabinalol, in 1898. Synthesis of its structural isomers yielded the first synthetic cannabinoid years later— Δ^9 -tetrahydrocannabinol (THC). Cannabinalol was previously shown to lack psychoactive effects, but this new compound demonstrated similar effects to cannabis in a model of ataxia in dogs. Pure Δ^9 -THC was subsequently isolated from hashish extract in 1964, and the structure was elucidated in 1967.⁹²

Marijuana was used as an intoxicant from the 1850s until the 1930s when the US Federal Bureau of Narcotics began to portray marijuana as a powerful, addicting substance. Despite this, marijuana was listed in the US Pharmacopoeia from 1850–1942. In 1970, the Controlled Substances Act classified marijuana as a Schedule I drug.

In all populations, cannabis use by males exceeds use by females. Currently, marijuana is the most commonly used illicit xenobiotic in the United States, yet it is legal in states such as Colorado and Washington. A study by the Substance Abuse and Mental Health Services Administration reported that in 2006 in the United States, 6.0% (14.8 million persons) 12 years of age or older used marijuana in the month prior to the survey; this prevalence is unchanged from previous years. The prevalence of past-month users aged 12 to 17 years was 6.7% (down from 8.2% in 2002). The number of first-time users was estimated to be 2.1 million, with 63.3% younger than 18 years of age.

Interest in synthetic cannabinoid receptor agonists (SCRAs) as potential therapeutics increased following the progress of the late 1960's, and several SCRAs similar in structure to THC were created. These semisynthetic compounds were based on the dibenzopyran ring structure of THC and had varying cannabinoid receptor binding affinity relative to THC. The search for a nonopioid analgesic sparked research and development efforts by pharmaceutical companies, most notably Pfizer, from the 1960s to 1980s.⁶³ Despite its efforts, no drugs came to market; new agents retained unwanted psychoactive side effects. During this period, extensive structure activity relationships for cannabinoids were developed.⁶²

Subsequent synthetic compounds were developed as cannabinoid research tools and were important in the discovery of central and peripheral cannabinoid receptors (CB₁ and CB₂) in the 1980s.³² Many of these did not retain chemical similarity to THC but remained potent and efficacious agonists at CB₁ and CB₂.⁶² In the 1990s, the endogenous cannabinoids were discovered and have been since synthesized.⁸⁰ These free fatty acids are quickly hydrolyzed in vivo, a fact that previously limited potential for pharmaceutical development. More recently stable versions of endocannabinoids have been made (Fig. 77–1).

In 2004, SCRA-laced herbal incense blends began to be available over the Internet and through smoke shops in

Western Europe.⁸⁴ Popular use and subsequent publicity increased resulting in several users presenting to emergency departments in Germany. As the result of efforts by the German government and THC Pharma, JWH-018 was isolated as the psychoactive ingredient present in these early incense blends. The discovery led to legislative action and subsequent ban of herbal incense—containing JWH-018 in Germany, but almost as soon as the ban took effect, incense manufacturers simply switched to a different SCRA—JWH-073. Since that time, many Western European countries have further legislated control of SCRA.

Incidence of exposure in the United States has been increasing over the past 3 years, and in November 2010, the Drug Enforcement Administration (DEA) began the process of declaring selected SCRA to be Schedule I substances on a temporary basis. As of March 2011, the DEA has listed several nonclassical cannabinoids as Schedule I, but as was the case in Germany, manufacturers have switched to other SCRA not yet scheduled and even marketed the products as such.

MEDICAL USES

Marijuana has been used medicinally for thousands of years to treat a seemingly endless array of conditions. However, modern medicine is burdened by an evidence-based system rather than the belief-based medicine of old. Therefore, potential medicinals must be proven through rigorous investigation to be not only safe but efficacious in the treatment of a targeted malady. While smoked marijuana and THC preparations have not proved overly dangerous in published studies, questionable efficacy has been demonstrated. Several issues must be considered when examining the body of evidence both for and against the medical use of cannabinoids. Marijuana is not the same entity as, nor is interchangeable with, Δ^9 -THC. While the latter may be the chief psychoactive constituent of marijuana, the multiple additional cannabinoids present in marijuana are biologically active and must be considered. Secondly, significant study design flaws limit the conclusions that can be drawn from existing studies. Finally, poor overall understanding of cannabinoid physiology may hamper future study design. Proposed uses for medical marijuana and the available evidence supporting that use are reviewed below.

Pain

Acute Pain. Studies examining the efficacy of THC in the setting of induced acute pain showed no improvement. These studies were limited by the lack of a positive control and examined only extremes of induced pain.²⁹ Smoked marijuana failed to attenuate thermal pain in volunteers, and an oral THC analog had no effect on postsurgical pain.⁶⁹

Chronic Pain. When used for the treatment of chronic and neuropathic pain, cannabinoids have had more favorable outcomes in published studies although design flaws severely limit the quality of evidence for medical use.¹⁰⁹ Initial trials of combined cannabinoid opioid therapy have been encouraging, and the principle may have mechanistic merit based on the knowledge that opioid and cannabinoid receptors can form heterodimers,¹²⁰ but lack of proper controls and the presence of confounders limit the accepted clinical applicability of cannabinoids as analgesics at this time.

Nausea and Vomiting

Trials of cannabinoids for treatment of chemotherapy-induced nausea and vomiting have repeatedly shown that serotonin antagonists such as ondansetron are superior compared to smoked marijuana or oral synthetic preparations.

Glaucoma

Trials investigating the efficacy of cannabinoids for the treatment of glaucoma have demonstrated their inferiority to longer acting traditional therapeutics, which have more significant effects on intraocular pressure and longer durations of effect.

Summary of Medical Use

In 2003, the Institute of Medicine undertook an extensive review of the evidence supporting the medical use of marijuana. It concluded that in some circumstances, cannabinoids show promise for use as therapeutics but the quality of current studies necessitated further research specifically for the treatment of chronic pain. In addition, smoked marijuana is a crude and unpredictable delivery mechanism, and safer, more precise methods of administration are needed.¹⁵² No data reviewed since that publication is sufficient to reverse that opinion.

Pharmaceutical cannabinoids are proposed for use in the management of many clinical conditions (Table 77–1) but have generally been approved only for the control of chemotherapy-related nausea and vomiting that are resistant to conventional antiemetics, for breakthrough postoperative nausea and vomiting, and for appetite stimulation in human immunodeficiency virus (HIV) patients with anorexia-cachexia syndrome.⁵⁵ The claims of benefit in the other medical conditions in Table 77–1 are not supported by evidence.^{6,154}

PHARMACOLOGY AND PATHOPHYSIOLOGY

The term “cannabinoid” refers to compounds that bind to and agonize the cannabinoid receptors regardless of whether they are derived from plants (phytocannabinoids), synthetic processes (synthetic cannabinoid receptor agonists), or endogenously existing neuromodulators (endocannabinoids). At one time the term may have been used to delineate a structural similarity to Δ^9 -THC, but this naming convention has largely been abandoned during the past 30 years of cannabinoid research as new compounds have been discovered and synthesized. The structural diversity of cannabinoid ligands and the absence of a true pharmacophore make nomenclature based purely on structure cumbersome and inconsistent. It is preferable then to use the term cannabinoid to denote receptor agonism and subclassify cannabinoids further based on origin and structure (Fig. 77–1).

Cannabis is a collective term referring to the bioactive substances from the Cannabis plant. The Cannabis genus (species sativa and indica) produces more than 60 chemicals (C21 group) called cannabinoids. In this chapter, the term “cannabis” encompasses all cannabis products. The major cannabinoids are cannabitol, cannabidiol (CBD), and tetrahydrocannabinol. The principal psychoactive cannabinoid is THC, or Δ^9 -tetrahydrocannabinol. Marijuana is the common name for a mixture of dried leaves and flowers of the C. sativa plant. Hashish and hashish oil are the pressed resin and the oil expressed from the pressed resin, respectively. The concentration of THC varies from 1% in low-grade marijuana up to 50% in hash oil. THC extracted from marijuana using butane (butane hash oil or BHO) can approach THC concentrations of 100%. Pure THC and a SCRA are available by prescription with the generic names of dronabinol and nabilone, respectively. Nabiximols is the generic name for an oral mucosal spray containing THC and cannabidiol, which is approved for medical use in Canada, the United Kingdom, and parts of Europe. Unregulated SCRA originally designed as research chemicals have emerged as designer drugs of abuse over the past 6 years.

Cannabinoid receptors are G protein linked neuromodulators that inhibit adenylate cyclase in a dose-dependent and stereospecific manner. While historically the cannabinoid receptor system is described as having a central CB₁ and a peripheral CB₂ receptor, recent evidence points to the central nervous system (CNS) presence of CB₂ receptors.¹³⁴ The two currently identified cannabinoid receptors are labeled CB₁ and CB₂ and are distinguished largely by their anatomic distribution and mechanisms of cellular messaging (Fig. 77–2).

FIGURE 77–2. Endocannabinoids act as allosteric cellular messengers. In response to presynaptic γ -aminobutyric acid (GABA) release and postsynaptic binding resulting in increased cyclic AMP, endocannabinoids are synthesized on demand and bind to presynaptic cannabinoid receptors. Activation of these G protein receptors results in decreased presynaptic adenylyl cyclase, decreased cAMP, decreased calcium ion influx and increased potassium efflux. The net result is hyperpolarization of the presynaptic cell and decreased neurotransmitter release. After binding, endocannabinoids diffuse back to the post synaptic area where they undergo degradation by MAG lipase and fatty acid amide hydrolase. CB₁R = cannabinoid type 1 receptor; MPAK = mitogen-activated protein kinase; MAG lipase = monoacylglycerol lipase; DAG lipase = diacylglycerol lipase. (Adapted with permission from Seely KA, Prather PL, James LP, Moran JH: Marijuana-based drugs: innovative therapeutics or designer drugs of abuse? Mol Interv. 2011;11:36–51.)

CB₁ Receptors and the Psychogenic Effects of Cannabis

CB₁ receptors are the most numerous G protein coupled receptors in the mammalian brain accounting for the multiple and varied effects of Cannabis on behavior, learning, and mood as well as suggesting the enormous complexity of the endocannabinoid system.⁵⁴ The highest concentration of CB₁ receptors are located in areas of the brain associated with movement and higher functions of cognition and emotions. Relative lack of CB₁ receptors in the brainstem also explains lack of coma and respiratory depression seen with Cannabis use. CB₁ receptors are structurally comprised of seven transmembrane protein units coupled to pertussis-sensitive (decrease adenylate cyclase) G proteins. They exhibit genetic variation via splice variants and are found as heterodimers with a multitude of other receptor types.⁶³

CB₂ receptors have traditionally been thought of as existing in the periphery and mainly affecting immune response, although evidence now exists of their activity in the CNS. Isolated agonism of CB₂ receptors has been the target for novel pharmaceutical candidates as antiinflammatory agents with minimal success as psychoactive effects of CB₁ agonism were still evident.

Mechanism of Cellular Signaling

Cannabinoid receptors both in the CNS and in the periphery exist on the presynaptic terminus of various neurons. Depolarization in postsynaptic portion of the neuron and subsequent increase in intracellular Ca²⁺ leads to on-demand synthesis and release of endocannabinoids.¹⁰⁸ These free fatty acid-based messengers diffuse into the synapse and bind to the presynaptic cannabinoid receptor. Ligand binding causes conformational change in the G protein subunits and inhibition of adenylate cyclase, resulting in decreased intracellular cAMP concentrations, decreased activity of voltage-gated Ca²⁺ channels, and ultimately decreased neurotransmitter release (Fig. 77–2). Exogenous cannabinoids act in much the same way compared to endogenous compounds after receptor binding, except that binding affinity will vary among ligands and endogenous cannabinoids are rapidly metabolized by hydrolases.⁸⁰ Interestingly, some online chemical suppliers offer fatty acid amide hydrolase inhibitors for sale, along with various SCRAAs, perhaps providing a glimpse into future products more closely related to endocannabinoids coming to market.

Both receptors inhibit adenylate cyclase and stimulate K⁺ channel conductance.¹¹² CB₁ receptors are located either presynaptically or postsynaptically and their activation can inhibit or enhance the release of acetylcholine, L-glutamate, γ -aminobutyric acid, noradrenaline, dopamine, and 5-hydroxytryptamine.^{67,73,127}

The neuropharmacologic mechanisms by which cannabinoids produce their psychoactive effects have not been fully elucidated.^{56,67,112} Nevertheless, activity at the CB₁ receptors is believed to be responsible for the clinical effects of cannabinoids,^{12,37,67,140} including the regulation of cognition, memory, motor activities, nociception, and nausea and vomiting. Chronic administration of a cannabinoid agonist reduces CB₁ receptor density in several regions of the rat brain.¹³

PHARMACOKINETICS AND TOXICOKINETICS

Absorption

The pharmacokinetics of phytocannabinoids have been extensively reviewed.⁴⁷ The rate and completeness of absorption of cannabinoids depend on the route of administration and the type of cannabis product.

Inhalation of smoke containing THC results in the onset of psychoactive effects within minutes. From 10% to 35% of available THC is absorbed during smoking, and peak serum THC concentrations occur an average of 8 minutes (range, 3–10 minutes) after the onset of smoking marijuana. Peak serum concentrations depend on the dose. A marijuana cigarette containing 1.75% THC produces a peak serum THC concentration of approximately 85 ng/mL.⁵⁹

Ingestion of cannabis results in an unpredictable onset of psychoactive effects in 1 to 3 hours. Only 5% to 20% of available THC reaches the systemic circulation following ingestion. Peak serum THC concentrations usually occur 2 to 4 hours after ingestion, but delays up to 6 hours are described.⁸² Dronabinol has an oral bioavailability of approximately 10% with high interindividual variability.^{44,103} THC is detectable in serum 1.5 to 4.5 hours after ingestion of dronabinol; peak serum concentrations occur within 4 hours after ingestion.⁴³ Nabilone has an oral bioavailability estimated to be greater than 90% and reaches peak serum concentrations 2 hours after ingestion.¹²⁵ The therapeutic serum THC concentration for the treatment of nausea and vomiting is greater than 10 ng/mL.²²

Distribution

THC has a steady-state volume of distribution of approximately 2.5 to 3.5 L/kg.⁴⁷ Cannabinoids are lipid soluble and

accumulate in fatty tissue in a biphasic pattern. Initially, THC is distributed to highly vascularized tissues such as the liver, kidneys, heart, and muscle. Following smoking or intravenous administration, the distribution half-life is less than 10 minutes.⁶⁰ After the initial distribution phase, THC accumulates more slowly in less vascularized tissues and body fat. Repeated administration of Δ^8 -THC (an isomer of Δ^9 -THC) to rats over 2 weeks resulted in steadily increasing concentrations of Δ^8 -THC in body fat and liver but not in brain tissue. Once administration of Δ^8 -THC stopped, the cannabinoids were slowly released from fat stores as adipose tissue turned over.¹⁰⁷

THC crosses the placenta and enters the breast milk. Concentrations in fetal serum are 10% to 30% of maternal concentrations. Daily marijuana smoking by a nursing mother resulted in concentrations of THC in breast milk eightfold higher than concomitant maternal serum concentrations; THC metabolites do not accumulate in breast milk.¹¹⁴

Metabolism

THC is nearly completely metabolized by hepatic microsomal hydroxylation and oxidation (primarily CYP2C9 and CYP3A4).⁴⁷ The primary metabolite (11-hydroxy- Δ^9 -THC or 11-OH-THC) is active and is subsequently oxidized to the inactive 11-nor- Δ^9 -THC carboxylic acid metabolite (THC-COOH) and many other inactive metabolites.^{14,118}

The serum concentrations of THC and its metabolites change over time. Smoking a marijuana cigarette results in peak serum THC concentrations before finishing the cigarette. In six volunteers, peak serum THC concentrations occurred at 8 minutes (range, 6–10 minutes) after onset of smoking, peak 11-OH-THC at 13 minutes (range, 9–23 minutes), and peak THC-COOH at 120 minutes (range, 48–240 minutes) (Fig. 77–3).⁵⁹ Approximately 1 hour after beginning to smoke a marijuana cigarette, the THC to 11-OH-THC ratio is 3:1, and the THC to THC-COOH ratio is 1:2; at approximately 2 hours the ratios are 2.5:1 and 1:8, respectively; and at 3 hours the ratios are 2:1 and 1:16, respectively.⁵⁹ Ingestion of cannabis results in much more variable concentrations and time courses of THC and metabolites (Fig. 77–3). Nonetheless, at 2 to 3 hours postingestion, the ratios are similar to those after smoking: THC to 11-OH-THC is 2:1 and THC to THC-COOH ranges from 1:7 to 1:14.¹⁵⁰

FIGURE 77–3. Estimated relative time course of THC and its major metabolite in the urine based on the route of exposure. THC = Δ^9 tetrahydrocannabinol; THC-COOH = Δ^9 THC carboxylic acid.

Of the many aminoalkylindole (AAI) SCRAAs isolated in “Spice” incense blends, human metabolic analyses have been published for JWH-018, JWH-073, and AM 2201.^{14,15} In contrast to THC, these cannabinoids are metabolized largely through hydroxylation and oxidation by CYP2C9 and CYP1A2 (with minor contributions of CYP2D6) to active metabolites that retain affinity for and in most are agonists at both CB₁ and CB₂ receptors.^{26,27} These metabolites undergo glucuronic acid conjugation in phase II metabolism.

Excretion

Reported elimination half-lives of THC and its major metabolites vary considerably. Following intravenous doses of THC, the mean elimination half-life ranges from 1.6 to 57 hours.⁴⁷ Elimination half-lives are expected to be similar following inhalation.^{47,59} The elimination half-life of 11-OH-THC is 12 to 36 hours, and the elimination half-life of THC-COOH ranges from 1 to 6 days.^{75,150}

THC and its metabolites are excreted in the urine and the feces. In the 72 hours following ingestion, approximately 15% of a THC dose is excreted in the urine and roughly 50% is excreted in the feces.^{1,20,153} Following intravenous

administration, approximately 15% of a THC dose is excreted in the urine and only 25% to 35% is excreted in the feces.¹⁵⁰ Inhalation is expected to produce results similar to intravenous administration.^{47,59} In 5 days, 80% to 90% of a THC dose is excreted from the body.^{51,64}

Cannabinoids were measured in the urine following smoking a marijuana cigarette containing 27 mg of THC (Fig. 77–3).⁸⁸ THC urine concentrations peaked at 2 hours (mean, 21.5 ng/mL; range, 3.2–53.3 ng/mL) after smoking and were undetectable (<1.5 ng/mL) in five of the eight subjects by 6 hours after smoking. Urine concentrations of 11-OH-THC peaked at 3 hours (77.3 ± 29.7 ng/mL). The primary urinary metabolite is the glucuronide conjugate of THC-COOH.¹⁵⁴ THC-COOH urine concentrations peak at 4 hours (179.4 ± 146.9 ng/mL),⁸⁹ and it has an average urinary excretion half-life of 2 to 3 days (range: 0.9–9.8 days).⁴⁷ Both 11-OH-THC and THC-COOH remained detectable in the urine of all eight subjects for the 8 hours of the study.⁸⁸

Following discontinuation of use, metabolites may be detected in the urine of chronic users for several weeks.^{36,70} Factors such as age, weight, and frequency of use only partially explained the long excretion period.³⁶

Primary urinary metabolites of nonclassical SCRA are summarized in Fig. 77–4.

FIGURE 77-4. JWH-018 and AM2201 metabolism. Aminoalkylindole synthetic cannabinoid JWH-018 and its omega fluorinated analog AM2201 undergo oxidation by CYP2C9 and CYP1A9 to primary metabolites that retain affinity and ability to bind with cannabinoid receptors. One JWH-018 primary metabolite, acts as a antagonist at CB₁. Secondary metabolites are formed by conjugation. These metabolites may retain ability to bind to cannabinoid receptors but at this

time it is clear which do so and in what capacity (agonist, antagonist, or inverse agonist). (Adapted with permission from Chimalakonda KC, Seely KA, Bratton SM, et al.: Cytochrome P450-mediated oxidative metabolism of abused synthetic cannabinoids found in K2/Spice: identification of novel cannabinoid receptor ligands. *Drug Metab Dispos.* 2012;40:2174–2184.)

CLINICAL MANIFESTATIONS

The clinical effects of THC use, including time of onset and duration of effect, vary with the dose, the route of administration (ingestion is slower in onset than inhalation), the experience of the user, the vulnerability of the user to psychoactive effects, and the setting in which the drug is used. The concomitant use of CNS depressants such as ethanol, or stimulants such as cocaine, alters the psychological and physiologic effects of marijuana.

Psychological Effects

Use of marijuana produces variable psychological effects.³⁷ The variation, which occurs both between and within users, may be a result of drug tolerance, level or phase of clinical effects, strain of cannabis, physical and social settings, or user expectations or cognitive set. The most commonly self-reported effect is relaxation. Other commonly reported effects are perceptual alterations (heightened sensory awareness, slowing of time), a feeling of well-being (including giddiness or laughter), and increased appetite.⁴⁶

Physiologic Effects

Use of cannabis is associated with physiologic effects on cerebral blood flow, the heart, the lungs, and the eyes. In a controlled, double-blind positron emission tomography study,⁸⁹ intravenous THC increased cerebral blood flow, particularly in the frontal cortex, insula, cingulate gyrus, and subcortical regions. These increases in cerebral blood flow occurred 30 to 60 minutes after use and were still elevated at 120 minutes.⁹⁰ Similar blood flow changes result from smoking marijuana.¹¹¹

Common acute cardiovascular effects of cannabis use include increases in heart rate and decreases in vascular resistance.^{71,135} Cannabis produces dose-dependent increases in heart rate within 15 minutes of starting a marijuana cigarette (from a baseline mean of 66 beats/min to a mean of 89 beats/min) that reach a maximum (mean, 92 beats/min) 10 to 15 minutes after peak serum THC concentrations. These changes last for 2 to 3 hours.⁸ Increases in blood pressure may occur with cannabis use. In a study of six subjects, an increase in blood pressure from a baseline mean of 119/74 mm Hg to a mean of 129/81 mm Hg occurred but was not statistically significant.⁸ In a double-blind, controlled study of men being investigated for angina pectoris, smoking a marijuana cigarette resulted in statistically significant changes in blood pressure from a baseline mean of 123/79 mm Hg to a peak mean of 132/84 mm Hg.¹¹⁹ In contrast, repeated THC use resulted in significant slowing of heart rate (from a mean of 68 beats/min to a low of 62 beats/min) and lowering of blood pressure (from a mean of 116/62 mm Hg to a low of 108/53 mm Hg).¹⁰ Decreased vascular tone may cause postural hypotension accompanied by dizziness and syncope.

Inhalation or ingestion of THC produces a dose-related short-term decrease in airway resistance and an increase in airway conductance in both normal and asthmatic individuals.¹⁴² Smoking marijuana results in an immediate increase in airway conductance, which peaks at 15 minutes and lasts 60 minutes. Ingestion of cannabis produces a significant increase in airway conductance at 30 minutes, which peaks at 3 hours and lasts 4 to 6 hours.^{143,144,147} The mechanism for this effect is unclear.

The principal ocular effects of cannabis are conjunctival injection and decreased intraocular pressure. Cannabinoids, applied topically to a rabbit eye, resulted in hyperemia of the conjunctival blood vessels 2 hours after application.⁹⁶ Regardless of route of administration, cannabis causes a fall in intraocular pressure in 60% of users⁴⁵ by acting on CB₁ receptors in the ciliary body.¹¹⁷ The mean reduction in intraocular pressure is 25% and lasts 3 to 4 hours.

Physiological effects of novel SCRAAs have not been studied in any controlled settings.

ACUTE TOXICITY

In addition to the physiologic and psychological effects described above, acute toxicity may include decreases in coordination, muscle strength, and hand steadiness. Lethargy, sedation, postural hypotension, inability to concentrate, decreased psychomotor activity, slurred speech, and slow reaction time also may occur.^{106,153}

In young children, the acute ingestion of cannabis is potentially life threatening.⁸⁷ Ingestion of estimated amounts of 250 to 1000 mg of hashish resulted in obtundation in 30 to 75 minutes. Tachycardia (>150 beats/min) was found in one third of the children. Less commonly reported findings include apnea, cyanosis, bradycardia, hypotonia, and opisthotonus.

The acute toxicity profile of nonclassical SCRA stands in stark contrast to the relatively mild effects of smoked or ingested phytocannabinoid products and surprised both users and clinicians, who expected effects to be largely identical to marijuana and hashish. This is likely a result of AAI cannabinoids found in incense blends being more potent and efficacious at cannabinoid receptors as well as having active metabolites. Moreover, these products are unregulated, and the presence of additional contaminating xenobiotics, such as designer cathinones, methylxanthines, and long-acting β -adrenergic agonists such as clenbuterol must be considered.

Deciphering the recent case literature of SCRA toxicity is fraught with challenges as many of the published reports lack laboratory confirmation of exposure. In addition, cases involving spice blends carry the possibility that some adverse effects could result from the plant matter found with the SCRA. Finally, the concentration of SCRA varies by incense package, even of the same brand and lot, making dose estimation difficult if not impossible.

Agitation¹²⁹ and seizures are reported.^{81,128} In one report with laboratory confirmation, a patient experienced multiple seizures within 30 minutes after ingesting JWH-018 in powder form.⁸¹ The sample was confirmed as pure JWH-018, and it was later further analyzed, as was the patient's blood and urine, for the presence of cathinones or other xenobiotic contaminants, with none detected.

Psychosis (new onset, acute exacerbation of existing psychiatric disorders, and increased risk of psychosis relapse) and anxiety have resulted even after single doses.^{53,65,115}

Tachycardia was a common finding detailed in one series, and tachydysrhythmia requiring cardioversion has been described.⁸¹ Chest pain and increased troponin concentrations were observed in three patients who claimed to have smoked spice several days before presenting to hospital, but laboratory confirmation of SCRA exposure was not performed.⁹⁷

Diffuse pulmonary infiltrates and dyspnea requiring intubation and mechanical ventilation were reported in a habitual spice user. Laboratory confirmation revealed three parent SCRA (AM2201, JWH-122, and JWH-210).²

Accounts of acute kidney injury are described in a case series of 16 previously healthy patients. All patients reported smoking spice incense blends prior to presentation. The patients had flank pain, nausea, and vomiting with elevated serum creatinine concentrations. Laboratory confirmation was achieved in eight of the patients and a previously unreported SCRA was isolated (XLR-11). Several of the patients required hemodialysis, but all eventually recovered.¹⁰¹

ADVERSE REACTIONS

Acute Use

Cannabis users occasionally may experience distrust, dysphoria, fear, or panic reactions. Transient psychotic episodes are associated with cannabis use. Commonly reported adverse reactions at the prescribed dose of dronabinol or nabilone include postural hypotension, dizziness, sedation, xerostomia, abdominal discomfort, nausea, and vomiting. One case of acute pancreatitis (serum amylase concentration up to 3200 IU/mL) following a period of heavy cannabis use is reported, but the causal relationship is unclear.⁴⁴

Life-threatening ventricular tachycardia (200 beats/min) has been reported.¹²¹ In six individuals with acute cardiovascular deaths, postmortem whole-blood THC concentrations ranged from 2 to 22 ng/mL (mean, 7.2 ng/mL; median, 5 ng/mL).⁵ While the temporal association is clear, causality is less clear because three of the six people had significant preexisting cardiac pathology. The risk of myocardial infarction is increased five times over baseline in the 60 minutes after marijuana use but subsequently declines rapidly to baseline risk levels.⁹⁸ Atrial fibrillation with palpitations, nausea, and dizziness was temporally associated with smoking marijuana in four patients.^{38,79,138}

Chronic Use

Long-term use of cannabis is associated with a number of adverse effects.

Immune System. Cannabinoids affect host resistance to infection by modulating the secondary immune response (macrophages, T and B lymphocytes, acute phase and immune cytokines). However, an immune-mediated health risk from using cannabis has not been documented.⁷⁷

Respiratory System. Chronic use of marijuana is associated with clinical findings compatible with obstructive lung disease.¹⁴⁷ Smoking marijuana delivers more particulates to the lower respiratory tract than does smoking tobacco,¹⁵⁵ and marijuana smoke contains carcinogens similar to tobacco smoke. Case reports and a hospital-based case-control study suggest that cancers of the respiratory tract (mouth, larynx, sinuses, lung) are associated with daily or near daily smoking of marijuana, although exposure to tobacco smoke and ethanol may be confounding factors.^{21,142,145} A systematic review and a cohort study with 8 years of follow-up demonstrated no association between marijuana smoking and smoking-related cancers,^{49,93} and a population-based case-control study found that marijuana use was not associated with an increased risk of developing oral squamous cell carcinoma.¹²⁴

Cardiovascular System. Marijuana use may be a risk for individuals with coronary artery disease. An exploratory prospective study of self-reported marijuana use among patients admitted for myocardial infarction found that patients who used marijuana were at significantly increased risk for cardiovascular and noncardiovascular mortality compared with nonusers.^{98,103}

Reproductive System. Reduced fertility in chronic users is a result of oligospermia, abnormal menstruation, and decreased ovulation.¹⁷ Cannabis is a class C drug in pregnancy¹⁶ and affects birth weight and length but does not cause fetal malformations. Statistically significant reductions in birth weight (mean, 79 g less than nonusers) and length (mean, 0.5 cm shorter than nonusers) are reported in women who had urine assays positive for cannabis during pregnancy.¹⁵⁷ The results of three other studies are difficult to interpret because marijuana use in pregnancy was poorly documented.^{50,157} Epidemiologic studies based on self-reporting of cannabis use do not support an association between the use of cannabis during pregnancy and teratogenesis.^{78,85,157}

The effect of maternal use of cannabis during pregnancy on neurobehavioral development in the offspring has been studied. No detrimental effects are reported in children born to women who smoked marijuana daily (more than 21 cigarettes per week) in rural Jamaica.³⁴ Tremors and increased startle are reported in infants younger than 1 week of age whose mothers used cannabis during pregnancy.⁴⁰ These findings, which persisted beyond 3 days, were not associated with other signs of a withdrawal syndrome. There were no abnormalities in the children of parents who used greater than five cigarettes per week in Ottawa, Canada, at 12, 24, and 36 months of age, but lower scores in verbal and memory domains at 48 months of age are reported.^{39,41,51} The results of studies evaluating the effect of in utero exposure to cannabis on postnatal neurobehavioral development are equivocal because of methodologic concerns regarding exposure assessment and control of covariates,³¹ including the continued parental use of cannabis during the postnatal and early childhood periods. The role of second hand exposure to cannabis on postnatal and early childhood development of neurobehavioral problems has not been evaluated.

Endocrine System. In experimental animals, cannabis exposure is associated with suppression of gonadal steroids, growth hormone, prolactin, and thyroid hormone. In addition, cannabis alters the activity of the hypothalamic-pituitary-adrenal axis.¹⁷ In human studies, the results are inconsistent, long-term effects have not been convincingly demonstrated, and clinical consequences are undefined.¹⁷

Neurobehavioral Effects. There is a concern that chronic cannabis use results in deficits in cognition and learning that last well after cannabis use has stopped. Neuropsychological tests administered to 10 cannabis-dependent adolescents, eight adolescent noncannabis drug abusers, and nine nondrug users showed significant differences that persisted for the duration of the study (6 weeks of abstinence) between the cannabis group and the other groups in a visual retention test and a memory test.¹³² In a study of three experienced marijuana smokers, cannabis impaired arithmetic and recall tasks up to 24 hours after smoking.⁵² Adults who used cannabis more than seven times per week had impairments in math skills, verbal expression, and memory retrieval processes; people who used cannabis one to six times per week showed no impairments.¹¹ After 1 day of abstinence, 65 heavy marijuana users (median, use on 29 of past 30 days) showed greater impairment on neuropsychological tests of attention and executive functions than light marijuana users (median, use on 1 day of past 30 days).¹¹⁶ (The authors were uncertain whether this difference was caused by residual THC in the brain, a withdrawal effect from the drug, or a direct neurotoxic effect of cannabis.)

There is little evidence that adverse cognitive effects persist after stopping the use of cannabis⁶⁸ or that cannabis use causes psychosocial harm to the user.⁸⁶ The hypothesis that there is a causal association between cannabis use and psychosis has not been proven unequivocally.⁹ An “amotivational syndrome” is attributed to cannabis use. The syndrome is a poorly defined complex of characteristics such as apathy, underachievement, and lack of energy.^{25,131} The association of the syndrome with cannabis use is based primarily on anecdotal, uncontrolled observations.⁵⁶ Anthropologic field studies, evaluations of US college students, and controlled laboratory experiments have failed to identify a causal relationship between cannabis use and the amotivational syndrome.⁵⁶ A study evaluating the role of depression in the amotivational syndrome found significantly lower scores on “need for achievement” scales in heavy users (median, daily use for 6 years) with depressive symptoms compared with heavy users without depressive symptoms and light users (median, several times per month for 4.5 years) with or without depressive symptoms.¹⁰⁵ These data suggest that symptoms attributed to an amotivational syndrome are caused by depression, not cannabis. Another study found that behavior that could be interpreted as amotivation was inversely related to the perceived size of the reward.²⁵

Abuse, Dependence, and Withdrawal. The Diagnostic and Statistical Manual of Mental Disorders, 5th edition, defines marijuana abuse as repeated instances of use under hazardous conditions; repeated, clinically meaningful impairment in social/occupational/educational functioning; or legal problems related to marijuana use. Marijuana dependence is defined as tolerance, compulsive use, impaired control, and continued use despite physical and psychological problems caused or exacerbated by use. The amount, frequency, and duration of cannabis use required to develop dependence are not well established.^{24,141} Much of the support for cannabis dependence is based on the existence of a withdrawal syndrome. In

animals repeatedly given cannabis, the administration of a CB₁ receptor antagonist produced signs of withdrawal.^{83,139} In humans, chronic users experience unpleasant effects when abstaining from cannabis.¹⁸ The time of onset of withdrawal symptoms is not well characterized.¹⁷ The most reliably reported effects are irritability, restlessness, and nervousness as well as appetite and sleep disturbances.¹³⁹ Other reported acute withdrawal manifestations include tremor, diaphoresis, fever, and nausea. These symptoms and signs are reversed by the oral administration of THC.^{9,48} The duration of withdrawal manifestations, without treatment, is not clearly established.^{19,139}

There is a single report of a withdrawal syndrome observed after heavy and prolonged nonclassical SCRA use.

Cannabinoid Hyperemesis Syndrome. Chronic, heavy marijuana use is associated with a clinical syndrome comprised of abdominal discomfort, nausea, and hyperemesis. Symptoms are often refractory to opioids and antiemetics.¹⁵¹ The hallmark of the syndrome is almost immediate relief of symptoms with bathing or showering in hot water, and a major diagnostic feature is compulsive bathing. The pathophysiology of this syndrome is unclear. However, relief with hot water may indicate dysfunction of pain perception, excess substance P release, and activation of TRPV1 (a G protein receptor that has been shown to interact with the endocannabinoid system and is the only known capsaicin receptor); these may play a role in elucidating the mechanism for this syndrome as well as providing new treatment modalities. Ultimately, successful treatment of the cannabinoid hyperemesis syndrome depends on cessation of marijuana use.^{3,23,33,42,136,137,151}

CANNABIS AND DRIVING

The perceptual alterations caused by cannabis suggest that its recent use should be associated with automobile crashes. However, neither experimental nor epidemiologic studies have provided definitive answers about the effects cannabis use has on driving ability. The published analytical studies of the relationship between cannabis and driving behavior and motor vehicle crashes have been reviewed.⁷ In experimental driving studies, cannabis impairs driving ability, but cannabis-using drivers recognize their impairment and compensate for it by driving at slower speeds and increasing following distance. However, the slower reaction time caused by cannabis results in impaired emergency response behavior.

The epidemiologic studies evaluating the association of cannabis use and traffic crashes provide no evidence that cannabis alone increases the risk of causing fatal crashes or serious injuries.^{7,110} A recent study comparing past driving records of subjects entering a drug treatment center with controls found that a self-reported history of cannabis use was associated with a statistically significant increase in adjusted relative risk for all crashes (relative risk, 1.49; 95% confidence interval, 1.17–1.89) and for “at fault” crashes (relative risk, 1.68; 95% confidence interval, 1.21–2.34).²⁸

DIAGNOSTIC TESTING

Cannabinoids can be detected in plasma or urine. Enzyme-multiplied immunoassay technique (EMIT) and radioimmunoassay (RIA) are routinely available; gas chromatography–mass spectrometry (GC-MS) is the most specific assay and is used as the reference method.

EMIT is a qualitative urine test that is often used for screening purposes. EMIT identifies the metabolites of THC. In these tests, the concentrations of all metabolites present are additive. For the EMIT II Cannabinoid 20 ng Assay, the cutoff concentration for distinguishing positive from negative samples is 20 ng/mL. A positive test means that the total concentration of all the metabolites present in the urine was at least 20 ng/mL. A positive urine test for cannabis only indicates the presence of cannabinoids, and it does not identify which metabolites are present or in what concentrations. Qualitative urine test results do not indicate or measure intoxication or degree of exposure. The National Institute on Drug Abuse guidelines for urine testing specify test cutoff concentrations of 50 ng/mL for screening and 15 ng/mL for confirmation.

Variables affecting the duration of detection of urinary metabolites include dose, duration of use, acute versus chronic use, route of exposure, and sensitivity of the method. In addition, factors affecting the quantitative values of urine THC and metabolites include urine volume, concentration, and pH. Using GC/MS, metabolites may be detected in the urine up to 7 days following a single marijuana cigarette.^{60,61}

The length of time between stopping cannabis use and a negative EMIT urine test (<20 ng/mL) depends on the extent of use. Release of THC from adipose tissue is important in drug testing because chronic users may release cannabinoids in quantities sufficient to result in positive urine tests for several weeks. In addition, vigorous exercise may stimulate the release of cannabinoids from fat depots. In light users being tested daily under observed abstinence, the mean time to the first negative urine test is 8.5 days (range, 3–18 days) and the mean time to the last positive urine is 18.2 days (range, 7–34 days).³⁶ In heavy users (mean, 9 years of using at least once a day) being tested under the same conditions, the mean time to the first negative urine test result (EMIT assay <20 ng/mL) was 19.1 days (range, 3–46 days) and the mean time to the last positive urine sample was 31.5 days (range, 4–77 days).³⁶

Standard laboratory analyses identify THC and its metabolites but cannot identify the source of the THC (eg, marijuana,

hashish, dronabinol). EMIT will not identify nabilone because it is not THC; however, nabilone can be specifically identified using high-performance liquid chromatography–tandem mass spectrometry.¹²²

Immunoassays may give false-negative and false-positive test results (Table 77–2). To help identify evidence tampering, negative urine immunoassays should be accompanied by examining the urine for clarity and measuring urinary specific gravity, pH, temperature, and creatinine.^{133,148}

TABLE 77–2. Xenobiotics or Conditions Reported to Produce Inaccurate Screening Test Results for Tetrahydrocannabinol

<i>False Negative^a</i>	<i>False Positive</i>
Bleach (NaOCl)	Dronabinol
Citric acid	Efavirenz
Detergent additives	Ethacrynic acid
Dettol	Hemp seed oil
Dilution	Nonsteroidal antiinflammatory drugs
Glutaraldehyde	Promethazine
Lemon juice	Riboflavin
Potassium nitrite (KNO ₂)	
Table salt (NaCl)	
Tetrahydrozoline	
Vinegar (acetic acid)	
Water	

^aXenobiotics producing false negative urine tests are usually added to a urine sample, not ingested.

EMIT will not detect nonclassical SCRA metabolites. Commercial urine immunoassays are available but generally need to be directed to a specific SCRA. High-performance liquid chromatography–tandem mass spectrometry or gas chromatography mass spectrometry are currently the mainstay of laboratory confirmation for SCRA, but their clinical utility is limited in all but retrospective instances. Further challenges are presented by the multitude of known nonclassical cannabinoids and doubly so by the rate new SCRA are introduced to the illegal high market.^{46,66,72,74,99,100,123,146,149}

PASSIVE INHALATION

Studies of passive exposure to marijuana smoke and the urinary excretion of cannabinoids have used enclosed spaces with nonsmokers present during and after active smoking.^{30,82,102,110,113} In an unventilated 6.9 × 8.2 × 7.9-foot room (12,225.8 L of air), five adult volunteers were exposed to the side stream smoke of 4 or 16 marijuana cigarettes (THC, 25 mg/cigarette) smoked simultaneously over one hour on each of six consecutive days.³¹ After being exposed to four marijuana cigarettes, four of the volunteers had at least one positive urine by EMIT assay (cutoff, 20 ng/mL) at some unspecified time during the six study days; exposure to 16 marijuana cigarettes resulted in positive EMIT assays only after the second day of exposure.

In a car (1650 L of air), three adult volunteers were exposed to the smoke from 12 marijuana cigarettes smoked by two people over 30 minutes.¹⁰² EMIT analyses of urine samples from one passive inhaler were positive at time 0 to 4 hours and on days 2 and 3; a second passive inhaler had one positive urine test at time 4 to 24 hours after exposure.

Three adult volunteers in a 10 × 10 × 8-foot unventilated room (21,600 L of air) were exposed to the side stream smoke of four marijuana cigarettes (THC, 27 mg/cigarette) smoked simultaneously over one hour.¹⁰⁴ The concentrations of cannabinoids in urine samples taken 20 to 24 hours after exposure were less than 6 ng/mL when analyzed using RIA methodology. Another study used an unventilated room (total volume of 27,950 L) containing three desks and a filing cabinet.⁸² Over 10 to 34 minutes, each of six volunteers smoked a marijuana cigarette (THC, 17.1 mg/cigarette) and left the room. Four nonsmoking adult males were in the study room for 3 hours from the start of smoking. The door was opened and closed 18 times during the study. The maximum urine cannabinoid concentration (measured by RIA) in the nonsmokers was 6.8 ng/mL at 6 hours after the start of smoking.

Another study used a closed 8 × 8 × 10-foot room (15,500 L of air) with each of four subjects smoking two marijuana cigarettes containing 2.5% THC on one occasion and 2.8% THC on a second occasion.¹¹³ On each occasion, two nonsmoking subjects were in the room for one hour from the onset of smoking. None of the nonsmokers' urine samples (0–24 hours) from either exposure period tested positive on an EMIT assay with a cutoff of 20 ng/mL. An identical experiment in a closed car (approximately 3500 L of air) resulted in one of 23 urine specimens testing positive at 6 hours.

Therefore, passive inhalation of marijuana smoke is unlikely to result in positive urine test results unless the exposure has been extreme.

SALIVA

Saliva samples may be used to establish the presence of cannabinoids and time of cannabis consumption. Cannabinoids (THC, THC-COOH, 11-OH-THC) in saliva may be from the smoke of the marijuana or hashish or from a preliminary metabolism in the mouth.¹³⁰ Saliva THC concentrations above 10 ng/mL are consistent with recent use and correlate with subjective intoxication and heart rate changes.⁹⁴

HAIR

Hair sample analysis is not useful in identifying THC or its metabolites. Only small quantities of non-nitrogen-containing substances, such as cannabinoids, are found in hair pigments.^{35,76,95}

SWEAT

The analysis of perspiration to test for cannabinoids is a recent development. Perspiration deposits drug metabolites on the skin, and these are renewed even after the skin is washed. Detection threshold is reported to be 10 ng/mL, but forensic confirmation by alternative means is required.⁷⁶

ESTIMATING TIME OF EXPOSURE

A measurable serum concentration of THC is consistent with recent exposure and toxicity, but there is poor correlation between serum THC concentrations and actual clinical effects.⁵⁷ The ratio of THC to THC-COOH has been used to estimate time of smoking marijuana. Similar concentrations of each indicate cannabis use within 20 to 40 minutes and imply intoxication. In naive users, a concentration of THC-COOH that is greater than THC indicates that use probably occurred more than 30 minutes ago. The high background concentrations of THC-COOH in habitual users make estimations of time of exposure unreliable in this population.

Serum concentrations of THC and THC-COOH were used in a logarithmic equation to predict the time since smoking a marijuana cigarette.⁸⁸ The ratio provided acceptable results up to 3 hours after smoking (predicted time of exposure averaged 27 minutes longer than actual exposure time), but more than 3 hours after smoking the predicted exposure time was overestimated by 3 hours. Mean overestimations of predicted exposure time of 2.5 to 4.2 hours for smoking and of 1.6 hours for ingestions are reported when serum samples are taken more than 4 hours after exposure.⁵⁹

Chronic use or oral administration of cannabis increases the concentration of 11-OH-THC relative to the concentrations of THC or THC-COOH. In these cases, estimating time of exposure based on relative concentrations is problematic.⁵⁸ In four subjects, ingestion of cannabis produced total serum metabolite concentrations less than 20 times the serum THC concentration for 3 hours after ingestion, suggesting that a ratio of this magnitude is consistent with recent oral consumption.⁸²

MANAGEMENT

Gastrointestinal decontamination is not recommended for patients who ingest cannabis products, nabilone, or dronabinol because clinical toxicity is rarely serious and responds to supportive care. In addition, a patient with a significantly altered mental status, such as somnolence, agitation, or anxiety, has risks associated with gastrointestinal decontamination that outweigh the potential benefits of the intervention.

Agitation, anxiety, or transient psychotic episodes should be treated with quiet reassurance and benzodiazepines (midazolam 1–2 mg intramuscularly or diazepam 5–10 mg intravenously) as needed.

The toxicity of SCRAAs should not be expected to mirror that of THC or prescription THC-based cannabinoids. Aggressive supportive care may be necessary.

Psychomotor agitation, anxiety, and convulsions should be treated with benzodiazepines as above. Laboratory evaluation should be initiated for signs of electrolyte disturbances and direct toxicity of the CNS, cardiovascular, renal, and musculoskeletal systems. Aggressive crystalloid fluid resuscitation should be given for rhabdomyolysis and acute kidney injury.

Antipsychotics should be avoided during any phase of undifferentiated agitated delirium. Should psychotic features persist into a subacute time frame after the resolution of sympathomimetic features, antipsychotic medications can be considered. Patients should be observed until asymptomatic.

If available, drug samples along with the patient's blood and urine, while not clinically useful, may aid in unknown designer SCRA identification and understanding of clinical effects.

There are no specific antidotes for cannabis or SCRA toxicity. Coingestants, such as cocaine, ethanol, designer amphetamines, methylxanthines, and long-acting β -adrenergic agonists should be identified and their effects anticipated and treated as indicated.

SUMMARY

- Phytocannabinoids have been used for centuries both as medicinal substances and as intoxicants.
- Despite the collective human history with cannabinoids, we are only now beginning to understand the endocannabinoid system and the consequences of alterations to that system.
- Medical use of THC and smoked marijuana have long existed, and while the safety profile of these xenobiotics are established, evidence of the efficacy of medical marijuana over the gamut of currently prescribed maladies is sparse. Still, the cannabinoid system provides an attractive target system for treatment of chronic pain and appetite modulation, but more rigorous and properly designed investigations are needed.
- The toxicity profile of traditional cannabinoids and designer SCRAAs used as drugs of abuse and research chemicals are as different as their chemical structures. Clinicians, users, and public health policy makers alike would do well to separate these groups of cannabinoids in both thought and practice.

78 COCAINE

Jane M. Prosser and Robert S. Hoffman

HISTORY AND EPIDEMIOLOGY

Cocaine is contained in the leaves of *Erythroxylum coca*, a shrub that grows abundantly in Colombia, Peru, Bolivia, the West Indies, and Indonesia. As early as the 6th century, the inhabitants of Peru chewed or sucked on the leaves for social and religious reasons. In the 1100s, the Incas used cocaine-filled saliva as local anesthesia for ritual trephinations of the skull.⁶⁸

In 1859, Albert Niemann isolated cocaine as the active ingredient of the plant. By 1879, Vassili von Anrep demonstrated that cocaine could numb the tongue.¹⁰⁸ However, Europeans knew little about cocaine until 1884, when the Austrian ophthalmologist Karl Koller introduced cocaine as an effective local anesthetic for eye surgery and Koller's colleague, Sigmund Freud, wrote extensively on the psychoactive properties of cocaine.⁵⁵ Following these revelations, Merck, Europe's main cocaine producer, increased production from less than 0.75 pounds in 1883 to more than 150,000 pounds in 1886.¹⁰⁴

Simultaneously, reports of complications from the therapeutic use of cocaine began to appear. In 1886, a 25 year-old man had a "pulseless" syncope after cocaine was applied to his eye to remove a foreign body.²¹¹ By 1887, more than 30 cases of severe toxicity were reported,¹⁸¹ and by 1895 at least eight fatalities resulting from a variety of doses and routes of administration were summarized in one article.⁵⁷ Recreational cocaine use was legal in the United States until the passage of the Harrison Narcotic Act of 1914, when cocaine was restricted to medical use. Not until 1982, however, was the first cocaine-associated myocardial infarction reported in the United States.²⁸

Currently, cocaine is an approved pharmaceutical. It is used primarily for topical anesthesia of cutaneous lacerations or during otolaryngology procedures as a vasoconstrictor and topical anesthetic. Although multiple factors have fostered a decline in the medicinal use of cocaine,^{18,63,130} the recreational use of cocaine remains a significant problem.

The United Nations office on Drugs and Crime estimates that there are 13 to 19 million cocaine users worldwide.³⁴ In the United States, it is estimated that there are 1.5 million cocaine users.⁴³

PHARMACOLOGY

The alkaloid form of cocaine, benzoylmethylecgonine, is a weak base that is relatively insoluble in water. It is extracted from the leaf by mechanical degradation in the presence of a hydrocarbon. The resulting product is converted into a hydrochloride salt to yield a white powder, cocaine hydrochloride, which is very water soluble. Cocaine hydrochloride can be insufflated, applied topically to mucous membranes, dissolved in water and injected, or ingested; however, it degrades rapidly when pyrolyzed. Smokable cocaine (crack) is formed by dissolving cocaine hydrochloride in water and adding a strong base. A hydrocarbon solvent is added, the cocaine base is extracted into the organic phase, and then evaporated. The term "free-base" refers to the use of cocaine base in solution.

Cocaine is rapidly absorbed following all routes of exposure; however, when applied to mucous membranes or ingested, its vasoconstrictive properties slow the rate of absorption and delay the peak effect. Bioavailability for smoking cocaine exceeds 90%, and is approximately 80% following nasal application.¹⁰⁰ Data for ingested cocaine and application

to other mucous membranes such as the urethra, vagina, or rectum are inadequately documented. Table 78–1 lists the typical onsets and durations of action for various routes of cocaine exposure.

TABLE 78–1. Pharmacology of Cocaine by Various Routes of Administration

Route of Exposure	Onset of Action (minutes)	Peak Action (minutes)	Duration of Action (minutes)	Relative Peak Concentrations (ng/mL)
Intravenous	<1	3–5	30–60	180 ± 56
Nasal insufflation	1–5	20–30	60–120	220 ± 39
Smoking	<1	3–5	30–60	203 ± 88
Gastrointestinal	30–60	60–90	Unknown	Unknown

Following absorption cocaine is approximately 90% bound to plasma proteins, primarily α_1 -acid glycoprotein.¹⁶⁴ Based on human volunteer studies with small doses of cocaine, the volume of distribution is reported to be about 2.7 L/kg,¹⁰⁰ but it is unclear if the volume of distribution changes with overdose.

The metabolism of cocaine is complex and dependent on both genetic and acquired factors. Three major pathways of cocaine metabolism are well described (Fig. 78–1). Cocaine undergoes N-demethylation in the liver to form norcocaine, a minor metabolite that rarely accounts for more than 5% of drug.^{96,205} However, norcocaine readily crosses the blood–brain barrier and produces clinical effects in animals that are quite similar to cocaine.^{13,103,192} Nearly half of a dose of cocaine is both nonenzymatically²⁰⁴ and enzymatically hydrolyzed⁴¹ to form benzoylecgonine (BE). When BE is injected into animals, some reports suggest that it is virtually inactive,^{105,200} while other studies demonstrate cerebral vasoconstriction³² and seizures.^{112,146} When either injected directly into the cerebral ventricles^{147,192} or applied to the surface of cerebral arteries,¹³³ BE is a potent vasoconstrictor. Although BE traverses the blood–brain barrier poorly,¹⁴⁸ the potential effects are of concern as some BE is probably formed from cocaine that has already entered the central nervous system (CNS). In vitro, BE has little or no effect on cardiac sodium or potassium channels.^{32,49} Finally, plasma cholinesterase (PChE) and other esterases metabolize cocaine to ecgonine methyl ester (EME). In normal individuals, between 32% and 49% of cocaine is metabolized to EME.^{4,96} Like BE, EME crosses the blood–brain barrier poorly.¹⁴⁷ Although many authors state that EME has little or no pharmacologic activity,^{146,147,189} diverse animal models demonstrate contradictory results, concluding that EME is a vasodilator,^{133,162,190} sedative, anticonvulsant,¹⁹² and protective metabolite against lethal doses of cocaine.⁸¹

FIGURE 78–1. Metabolism of cocaine. The three principal metabolic pathways of cocaine are depicted.

The role of genetic or acquired alterations in PChE activity has been of interest for many years. Early in vitro studies showed that cocaine was poorly metabolized in serum from patients with succinylcholine sensitivity (low PChE activity). In subsequent studies and case series, patients with low PChE activity demonstrate increased sensitivity to cocaine,^{80,159} findings that are corroborated in multiple animal models.^{20,79,131}

Multiple other metabolites of cocaine are well characterized.³⁰ Several have clinical or diagnostic importance. In 1990, a unique metabolite was identified in patients who smoke cocaine, now known either as anhydroecgonine methyl ester (AEME) or methylecgonide.⁹⁸ The presence of this compound and its metabolite, ecgonidine, can be used to help determine the route of administration in cocaine users.¹⁸⁸ Additionally, AEME has demonstrable agonism at the muscarinic (M₂) receptors, which may have important clinical implications.²³⁰

Ethanol has a unique pharmacologic interaction with cocaine. A transesterification reaction between the two drugs produces benzoylethylecgonine, which is also called “ethyl cocaine” or “cocaethylene” (CE).¹³ In human volunteers given cocaine and ethanol, CE accounted for approximately 17% of the metabolites, producing a decrease in the amount of BE and an increase in the amount of EME formed.^{72,73} CE has a longer duration of action than cocaine and similar neurotoxic and cardiotoxic effects.

PATHOPHYSIOLOGY

Neurotransmitter Effects

Cocaine blocks the reuptake of biogenic amines. Specifically, these effects are described on serotonin and the catecholamines dopamine, norepinephrine, and epinephrine. Several animal investigations have elucidated the particular roles of each neurotransmitter. Mice lacking the dopamine transporter are relatively insensitive to the locomotor effects of cocaine.⁵⁹ Tachycardia emanates from adrenally derived epinephrine, whereas hypertension results from neuronally derived norepinephrine.^{209,210} Serotonin is an important modulator of dopamine and has a role in cocaine addiction, reward, and seizures.^{70,122,141}

Although much emphasis has been placed on the reuptake blockade of these biogenic amines, it is clear that this effect is insufficient to account for the clinical manifestations of cocaine toxicity. Other xenobiotics that block the reuptake of biogenic amines, such as cyclic antidepressants, produce quite distinct clinical manifestations²¹² (Chap. 71). Xenobiotics that block the effects of dopamine, epinephrine, and norepinephrine not only fail to protect against cocaine toxicity but actually exacerbate it.^{23,65,130,184} Although this may, in part, result from an unopposed α -adrenergic effect, hypertension and vasospasm fail to explain the increase in psychomotor agitation, seizures, and hyperthermia that result.^{23,65} These effects most likely result from an interaction between cocaine and excitatory amino acids. Cocaine increases excitatory amino acid concentrations in the brain,¹⁹⁹ and excitatory amino acid antagonists prevent both seizures and death in experimental animals.^{14,175} Finally, because experimental evidence in animals^{22,65,193} and clinical experience in humans demonstrate that sedation treats both the central effects of cocaine and the peripheral effects of biogenic amines, a newer model was proposed (Fig. 78–2). This model emphasizes the necessity of diffuse CNS excitation as a prerequisite for cocaine toxicity, explains experimental and clinical observations, and provides insight into the treatment of acute toxicity.

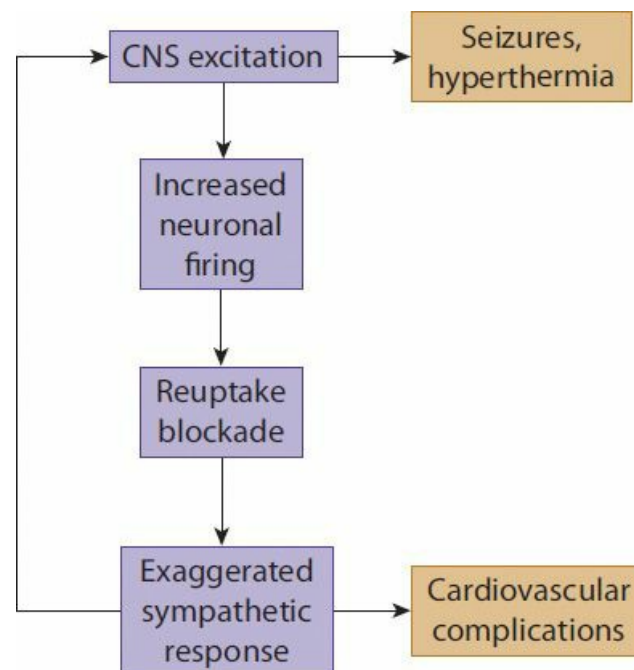

FIGURE 78–2. Cocaine induced central nervous system effects modulate peripheral events.

Cardiovascular Effects

Cocaine use is associated with myocardial ischemia and myocardial infarction (MI). The increased risk of MI results from several different mechanisms. Hypertension and tachycardia increase myocardial oxygen demand, induces vasospasm, accelerated atherogenesis, and hypercoagulability.

Vasospasm. Although increased myocardial oxygen demand may be sufficient to cause ischemia in some individuals, it is clear that cocaine also produces profound vasoconstriction. Evidence suggests that cocaine-induced vasoconstriction is mediated through both neuronal norepinephrine and BE.^{117,132} BE has a direct effect on vessels that appears to be calcium mediated.¹³² Additionally nicotine, which is simultaneously used by many substance users, has additive, if not synergistic, effects with cocaine.¹⁵²

Atherogenesis. Cocaine use accelerates atherosclerosis. Rabbits fed a normal diet supplemented with cholesterol do not develop atherosclerotic vascular disease. However, when that diet includes cocaine, rabbits develop classic atherosclerotic lesions.^{110,119,120} Experiments with human endothelial cells demonstrate that cocaine directly increases the permeability to lipids by altering tight junctions.¹¹¹ This probably promotes the formation of subendothelial atherosclerotic plaques.

Dysrhythmias. Like other local anesthetics (Chap. 67), cocaine blocks neuronal sodium channels, thereby preventing saltatory conduction. Because of homology between neuronal and cardiac sodium channels, cocaine also inhibits the rapid inward Na^+ current responsible for phase 0 depolarization of the cardiac action potential (Chaps. 16 and 71). Experimental evidence suggests that cocaine enters the sodium channel and binds on the inner membrane.^{35,109,169} Like many sodium channel blockers, binding is both pH and use dependent (ie, binding increases as pH falls or heart rate increases; Chap. 71).^{36,221} Furthermore, although norcocaine has a greater affinity for inactivated sodium channels, it has a much more rapid offset of action than cocaine.³⁵ Consequently, cocaine can be characterized as a Vaughan-Williams class 1C antidysrhythmic²²⁹ (Chap. 64). Cocaine-induced QRS prolongation is exacerbated by Vaughan-Williams class IA antidysrhythmics²²⁶ and ameliorated by hypertonic sodium bicarbonate, hypertonic sodium chloride, and lidocaine^{9,63,163}. Another effect of sodium channel blockade, the Brugada pattern, is also associated with cocaine use (Fig. 16–12).^{129,157}

In addition to its sodium channel-blocking properties, cocaine also blocks cardiac potassium channels (Chap. 16). This results in QT prolongation^{167,208,221} and may produce torsade de pointes.¹⁹¹ Cocaethylene also has dysrhythmogenic effects.¹⁵⁸ In vivo experiments demonstrated inhibition of the myocardial HERG potassium channels, which may explain this phenomenon.⁴⁹ In animal studies, CE is associated with increased incidence of dysrhythmias, prolonged myocardial depression, and increased lethality.^{105,225}

Hematologic Effects

Enhanced coagulation and impaired thrombolysis compound the effects of accelerated atherogenesis and vasospasm. Cocaine activates human platelets and causes α -granule release, resulting in platelet aggregation.^{75,116} Thus, even in the absence of endothelial injury, cocaine can initiate a thrombotic cascade while simultaneously enhancing the activity of plasminogen activator inhibitor type 1 (PAI-1), thereby impairing clot lysis.¹⁵¹

Pulmonary Effects

Bronchospasm. The association between cocaine use and asthma¹⁷⁸ was not recognized until smoked cocaine became prevalent.⁴⁷ Furthermore, experiments in human volunteers demonstrate that only smoked cocaine (not intravenous cocaine) produces bronchospasm.²⁰⁷ Although it is possible that bronchospasm results from direct administration of cocaine to the airways, inhaled contaminants of cocaine, or thermal insult, and the unique pyrolytic metabolite of cocaine that acts as a muscarinic agonist (AEME) produces bronchospasm in experimental animals.²⁵

CLINICAL MANIFESTATIONS

Many clinical manifestations of toxicity develop immediately following cocaine use. These are typically associated with the sympathetic overactivity, and their duration of effect is predictable based on the pharmacokinetics of cocaine use. Other manifestations, such as those associated with tissue ischemia, may present in a delayed fashion, with a clinical latency of hours to even days after last cocaine use. The reasons for this delay are not clear but may relate to the presence of an altered sensorium associated with acute cocaine use and its anesthetic effects (see Cessation of Use below).

Vital sign abnormalities that develop during cocaine toxicity are characteristic of the sympathomimetic toxic syndrome. Thus, varying degrees of hypertension, tachycardia, tachypnea, and hyperthermia occur. Although any of these vital sign abnormalities can be life threatening, experimental and clinical evidence suggests that hyperthermia is the most critical.^{23,65,138} Initially, with typically used doses, and at any time with a massive dose, apnea, hypotension, and bradycardia can result, all from direct suppression (anesthesia) of brainstem centers.^{117,130,144} These effects are fleeting and rarely noted when patients present to health care, as either the sympathetic overdrive rapidly ensues, or sudden death results. Additional sympathomimetic findings include mydriasis, diaphoresis, and neuropsychiatric manifestations.

Cocaine produces end-organ toxicity in virtually every organ system in the body. These events result from vasospasm, hemorrhage secondary to increased vascular shear force (dP/dT), or enhanced coagulation. Each organ system is discussed separately in the following sections.

Central Nervous System

Seizures, coma, headache, focal neurologic signs or symptoms, or behavioral abnormalities that persist longer than the predicted duration of effect of cocaine should alert the clinician to a potential catastrophic CNS event. Hemorrhage can occur at any anatomic site in the CNS. Subarachnoid, intraventricular, and intraparenchymal bleeding are all well described in association with cocaine use.^{2,39,125,136,171,194} Early discussions suggested an underlying predisposition due to the presence of arteriovenous malformations or congenital aneurysms,²²⁸ but subsequent larger studies failed to support this analysis, suggesting that effects can occur independently of preexisting disease.^{2,156,218} Ruptured intracerebral aneurysms in cocaine users are almost exclusively in the carotid artery circulation.^{2,156,218} Presumably, CNS bleeding is a manifestation of abnormal shear force. Spontaneous extraaxial bleeding is also associated with cocaine use.¹⁸³

Both vasospastic infarction and transient ischemic attack are reported in association with cocaine use.^{39,40,125} In one epidemiologic study, women younger than age 45 years who had strokes were seven times more likely to report cocaine use than controls.¹⁶⁸ Patients can present with any of the classic physical findings associated with thrombotic or embolic stroke. Vasospasm can injure the spinal cord, resulting in paralysis from an anterior spinal artery syndrome.^{39,150}

Seizures are commonly provoked by cocaine use.^{83,153} Cocaine use can serve as a trigger in patients with epilepsy, although an underlying focus is not necessary for seizures to occur.¹¹³

Headache is also well described in cocaine users. While the exact mechanism is unclear, hypertension or dysregulation of neurotransmitters may be contributory. In addition to typical tension headache, classic migraine and cluster headaches are also reported.^{166,185}

Eyes, Nose, and Throat

Sympathetic excess produces mydriasis through stimulation of the dilator fibers of the iris with characteristic retention of the ability to respond to light. Like other mydriatics, cocaine can produce acute narrow angle-closure glaucoma.⁷¹ Vasospasm of the retinal vessels causes both unilateral and bilateral loss of vision.^{82,127} Additionally, although cocaine produces excellent corneal anesthesia, it is highly toxic to the corneal epithelium. Following application of cocaine to the eye, the superficial corneal layer is shed, resulting in pain and decreased acuity.¹⁷² The loss of eyebrow and eyelash hair from thermal injury associated with smoking crack cocaine is called madarosis.²⁰⁶

Chronic intranasal insufflation of cocaine can produce perforation of the nasal septum. This finding most likely results from repeated ischemic injury with resultant cartilage loss. This ischemia is usually asymptomatic, and necrotic tissue is sloughed. At least one reported case of wound botulism (Chap. 41) has been associated with intranasal insufflation.

Presumably this resulted from accumulation of necrotic tissue in the nose, serving as a culture medium for *Clostridium botulinum*.¹¹⁵

Angioedema and oropharyngeal burns, located as far distally as the esophagus, are associated with smoking crack cocaine.^{21,26,107,145} These effects are most likely the result of inhalation or ingestion of superheated fumes and hot liquid (from the smoking apparatus) rather than direct toxicity from cocaine.

Pulmonary

Pneumothorax, pneumomediastinum, and pneumopericardium are reported following both smoked and intranasal cocaine use.^{134,173,187,212,215} These findings do not result directly from cocaine toxicity but rather are epiphenomena related to the mechanism of drug use. Following insufflation or inhalation, the user commonly performs a Valsalva maneuver in an attempt to retain the drug. Bearing down against a closed epiglottis increases intrathoracic pressure, and an alveolar bleb can rupture against the pleural, mediastinal, or pericardial surfaces.

Cocaine use exacerbates reversible airways disease, and it is common for patients to present with shortness of breath and wheezing.^{47,124,160,177} Like so many manifestations of cocaine toxicity, it is unclear whether this is a direct effect of cocaine or related to inhalation of some contaminant of the drug. However, as discussed above, the M₂ agonistic effects of the pyrolysis metabolite AEME might be contributory.

Crack lung is the term given to an acute pulmonary syndrome that occurs after inhalational use of crack cocaine. The syndrome is a poorly defined constellation of symptoms, including fever, hemoptysis, hypoxia, acute respiratory distress syndrome, and respiratory failure. It is associated with diffuse alveolar and interstitial infiltrates on chest radiography.¹⁷³ Histopathology shows diffuse alveolar damage and hemorrhage with inflammatory cell infiltration and hemosiderin-laden macrophages. Eosinophilia was noted in several cases.⁵³ The syndrome has been variously attributed to impurities mixed with the crack, carbonaceous material generated from pyrolysis, and direct cocaine toxicity.

Vasospasm and subsequent thrombosis of the pulmonary artery or its branches can produce pulmonary infarction.⁴² Patients present with shortness of breath and pleuritic chest pain characteristic of a pulmonary embolus. Clinical signs and symptoms of ventilation-perfusion (V/Q) mismatch ([Chap. 29](#)), as well as abnormalities on arterial blood gas analysis, are noted.

Cardiovascular

Chest pain or discomfort is a common emergency department complaint in cocaine users.¹⁷ Cocaine use is associated with cardiac ischemia and infarction in young people and may account for as much as 25% of myocardial infarctions in patients younger than 45 years of age.¹⁷⁰ Although myocardial infarction is of concern, only approximately 6% of patients with complaints referable to the heart will manifest biochemical evidence of myocardial injury.^{88,222} Many others will have an ischemic cardiac event, but for the remainder, the differential diagnosis is broad.¹¹⁸ Entities to consider include the pulmonary and esophageal etiologies described previously, referred abdominal symptoms (see [Abdominal](#)), chest wall injury,^{37,62,94,126,128} aortic dissection, coronary artery dissection,^{186,203} and dysrhythmias. No single sign or symptom or combination of signs and symptoms reliably identifies cardiovascular injury from among the discussed differential diagnosis.⁸⁸

Catecholamine-induced direct myocardial catecholamine toxicity contributes to both acute and chronic cardiac disease. Takotsubo cardiomyopathy is a reversible form of left ventricular apical ballooning associated with myocardial ischemia in the absence of atherosclerotic lesions. It is thought to result from catecholamine toxicity on the myocardium during high levels of stress and is also reported after cocaine use.⁵ Chronic cocaine use is associated with a dilated cardiomyopathy,^{76,118} the etiology of which is presumed to be the result of repeated subclinical ischemic events. Patients may present with signs and symptoms of congestive heart failure or pulmonary edema. The pathologic finding of contraction band necrosis also suggests that there may be some direct catecholamine toxicity as this finding only commonly occurs with cocaine and amphetamine use, pheochromocytoma, and in patients receiving high-dose vasopressors.^{51,219}

Abdominal

Abdominal pain, or other gastrointestinal complaints, suggests a broad differential diagnosis. Cocaine users have a disproportionate incidence of perforated ulcers.^{123,165,197} The etiology has not been elucidated but may be related to local ischemia of the gastrointestinal tract or increased acid production associated with sympathetic activity. Vasospasm produces ischemic colitis that can present with abdominal pain or bloody stools.^{128,155} More severe vasospasm, with or without thrombosis, can lead to intestinal infarction^{56,77,91,161} with attendant hypotension and metabolic acidosis. Signs and symptoms of bowel obstruction such as vomiting or distension might suggest body packing (gastrointestinal drug smuggling). Although less common, splenic¹⁵⁷ and renal infarctions^{44,149,182} may also occur. Spontaneous hemoperitoneum

is also reported, although occult trauma could not be definitively excluded.¹⁰

Animals frequently develop hepatotoxicity following cocaine administration. In human cocaine users, minor elevations of liver enzyme concentrations are common and rarely associated with symptoms.^{19,114} When more severe liver injury occurs, it is usually associated with multisystem organ dysfunction from hyperthermia or another type of hepatic injury.⁶ Isolated hepatic injury from cocaine is distinctly uncommon and may result from differences in metabolic pathways, as animals are known to make a hepatotoxic metabolite of cocaine that has not been described in humans.²¹⁷

Musculoskeletal

Rhabdomyolysis is common in all conditions that produce an agitated delirium and or hyperthermia; cocaine is no exception.^{31,93,179} Unlike most other toxicologic disorders, however, psychomotor agitation is not a prerequisite for cocaine-associated rhabdomyolysis.²³¹ Muscle injury may result from vasospasm or direct muscle toxicity; however, the mechanism remains unclear. Patients with cocaine toxicity present with a spectrum of illness that ranges from asymptomatic enzyme and electrolyte abnormalities characteristic of rhabdomyolysis, to localized or diffuse muscle pain, to frank compartment syndrome and acute kidney injury.⁴⁵

Limb ischemia associated with cocaine use is reported.⁶⁶ Vasospasm, accelerated atherogenesis, and increased thrombogenesis (see Pathophysiology) place users at increased risk.

Traumatic injury is also fairly common in the setting of cocaine use.¹⁴⁰ Clinicians should be aware of the possibilities of occult fractures or other injuries that may be masked by the anesthetic properties of cocaine or the patient's altered level of consciousness.^{130,139}

Neuropsychiatric

The neuropsychiatric effects of cocaine are most likely dose dependent. Low-dose administration produces alertness, exhilaration, hypersexual behavior, and other "desired" effects. These effects rarely bring users to health care facilities. As the cocaine dose increases, agitation, aggressive behavior, confusion, disorientation, and hallucinations can develop.

Other possible manifestations include a variety of movement disorders that most likely result from depletion or dysregulation of dopamine. Patients may develop acute dystonias^{22,50,216} or choreoathetoid movements that have been referred to as "crack-dancing."^{38,67}

Obstetrical

The majority of obstetrical findings associated with cocaine use involve developmental problems in the fetus and neonate and are probably a result of a combination of chronic vascular insufficiency from cocaine-induced spasm of the uterine artery or distal vessels and other risk factors, such as poor maternal nutrition, cigarette smoking, and a lack of prenatal care (Chap. 31). These events are extensively reviewed elsewhere.^{24,48,196} Acute cocaine use during pregnancy is associated with abruptio placentae, causing patients to present with abdominal pain and vaginal bleeding.^{1,52} The remaining maternal and fetal complications comprise every possible complication described in nonpregnant patients.

DIAGNOSTIC TESTING

Cocaine and benzoylecgonine, its principal metabolite, can be detected in blood, urine, saliva, hair, and meconium. Routine drug-of-abuse testing relies on urine testing using a variety of immunologic techniques (Chap. 6). Although cocaine is rapidly eliminated within just a few hours of use, BE is easily detected in the urine for 2 to 3 days following last use.⁴ When more sophisticated testing methodology is applied to chronic users, cocaine metabolites can be identified for several weeks following last use.²²⁴

Urine testing, even using rapid point-of-care assays, offers little to clinicians managing patients with presumed cocaine toxicity because it cannot distinguish recent from remote cocaine use. In addition, false-negative testing can result when there is a large quantity of urine in the bladder with very recent cocaine use or when the urine is intentionally diluted by increased fluid intake,²⁹ leading to a urine cocaine concentration below the cutoff value and interpretation of the test as negative. Under these circumstances, repeat testing is almost always positive. False-positive tests are extremely unlikely. However, external contamination is possible, particularly with hair testing.

While false-positive tests do occur, they are more common with hair testing than urine or blood because of the increased risk of external contamination.^{29,176} Because of the very low rate of false-positive results, confirmation of a positive urine is unnecessary for medical indications (Chap. 6).

The greatest benefit for cocaine testing is in cases of unintentional poisoning or suspected child abuse and neglect. Here confirmation of a clinical suspicion is essential to support a legal argument. In addition, there may be some usefulness for

urine testing of body packers, especially when the concealed xenobiotic is unknown.²¹⁴ While many body packers will have negative urine throughout their hospitalization, a positive urine test is suggestive of the concealed drug but obviously not confirmatory. More importantly, a conversion from a negative study on admission to a positive study not only confirms the substance ingested but also suggests packet leakage, which could be a harbinger of life-threatening toxicity (Special Considerations: SC5). Another indication for urine testing for cocaine occurs in young patients with chest pain syndromes where the history of drug use, specifically cocaine, is not forthcoming.⁸⁵ Routine diagnostic tests such as a bedside rapid reagent glucose, electrolytes, renal function tests, and markers of skeletal muscle and cardiac muscle injury are more likely to be useful than urine drug screening. An electrocardiogram (ECG) may show signs of ischemia or infarction, or dysrhythmias that require specific therapy. Unfortunately, in the setting of cocaine-associated chest pain, the ECG has neither the sensitivity nor the specificity necessary to permit exclusion or confirmation of cardiac injury.⁹⁰ Cardiac markers are therefore always required adjuncts when considering myocardial ischemia or infarction. Because cocaine use is associated with diffuse muscle injury, assays for troponin are preferred over myoglobin or myocardial band enzymes of creatine phosphokinase.⁸⁹ Additionally, computed tomography (CT) angiography of the coronary arteries has been reported to be a useful tool to exclude MI after cocaine use.²²⁰ This test exposes the patient to high levels of radiation, and relative risk versus benefit has not been studied. Chest radiography may be useful to exclude certain etiologies in patients with chest discomfort or to identify free air under the diaphragm when gastrointestinal perforation is suspected. Supplemental diagnostic studies, such as CT scans of the head, chest, or abdomen and functional cardiac imaging, should be guided by the clinical condition of the patient.^{33,46,69}

CESSATION OF USE

A cocaine withdrawal syndrome is not reported. Following binge use of cocaine, a “washed-out” syndrome occurs that is best described by dopamine depletion.^{202,213} Patients complain of anhedonia and lethargy, and they have trouble initiating and sustaining movement. However, they are arousable with minimal stimulation and usually remain cognitively intact.

Symptoms typically associated with cocaine toxicity can prevent in a delayed fashion after cessation of cocaine use. The reasons for this delay are multifactorial and not entirely apparent but may be related to prolonged elimination of metabolites such as CE; changes in receptor regulation¹⁵⁴; or affects on platelets, coagulation, and thrombolysis that incite a slow cascade leading to thrombosis.

MANAGEMENT

General Supportive Care

As in the case of all poisoned patients, the initial emphasis must be on stabilization and control of the patient’s airway, breathing, and circulation. If tracheal intubation is required, it is important to recognize that cocaine toxicity may be a relative contraindication to the use of succinylcholine.¹⁴² Specifically, in the setting of rhabdomyolysis, hyperkalemia may be exacerbated by succinylcholine administration, and life-threatening dysrhythmias may result (Chap. 69). Additionally, it is essential to recognize that PChE metabolizes both cocaine and succinylcholine.⁹⁹ Thus, their simultaneous use could either prolong cocaine toxicity or paralysis or both. Human data are insufficient to predict which interaction is more likely to occur. If hypotension is present, the initial approach should be infusion of intravenous 0.9% sodium chloride solution as many patients are volume depleted as a result of poor oral intake and excessive fluid losses from uncontrolled agitation, diaphoresis, and hyperthermia.

In the setting of cocaine toxicity it is important to recognize that both animal^{23,65} and human¹³⁸ experience suggests that elevated temperature represents the most critical vital sign abnormality. Determination of the core temperature is an essential element of the initial evaluation, even when patients are severely agitated. When hyperthermia is present, rapid cooling with ice water immersion preferably, or the combined use of mist and fanning, is required to achieve a rapid return to normal core body temperature (Chap. 30). Sedation or paralysis and intubation may be necessary to facilitate the rapid cooling process. Pharmacotherapy, including antipyretics, drugs that prevent shivering (chlorpromazine or meperidine), and dantrolene,⁵⁴ are not indicated as they are ineffective and have the potential for adverse drug interactions such as serotonin toxicity (meperidine) (Chap. 38) or seizures (chlorpromazine).

Sedation remains the mainstay of therapy in patients with cocaine-associated agitation. It is important to remember that cocaine use is associated with hypoglycemia due to catecholamine discharge.^{15,149} Clinical findings of hypoglycemia and increased catecholamines may be similar; consequently, a rapid bedside glucose should be obtained or hypertonic dextrose should be empirically administered if indicated, prior to or while simultaneously achieving sedation.

Both animal models^{23,65} and extensive clinical experience in humans support the central role of benzodiazepines. Antipsychotics have also been used in the treatment of acute cocaine intoxication. A meta-analysis evaluating benzodiazepines and antipsychotics in animal modes of cocaine toxicity found that both reduced mortality. However,

benzodiazepine treatment reduced mortality by 52% compared with only 29% for antipsychotics.⁷⁴ Although the choice among individual benzodiazepines is not well studied, an understanding of the pharmacology of these drugs allows for rational decision making. The goal is to use parenteral therapy with a drug that has a rapid onset and a rapid peak of action, making titration easy. Using this rationale, midazolam and diazepam are preferable to lorazepam, because significant delay to peak effect for lorazepam often results in oversedation when it is dosed rapidly or in prolonged agitation when the appropriate dosing interval is used. Drugs should be administered in initial doses that are consistent with routine practices and increased incrementally based on an appropriate understanding of their pharmacology. For example, if using diazepam, the starting dose might be 5–10 mg intravenously, which can be repeated every 3 to 5 minutes and increased if necessary. Large doses of benzodiazepines may be necessary (on the order of 1 mg/kg of diazepam). This may result from cocaine-induced alterations in benzodiazepine receptor function^{60,61,102} (Antidotes in Depth: A23).

On the rare occasion when benzodiazepines fail to achieve an adequate level of sedation, either a rapidly acting barbiturate or propofol should be administered. Controlled animal studies clearly show that the use of phenothiazines or butyrophenones is contraindicated.^{23,65,227} In animal models, these drugs enhance toxicity (seizures), lethality, or both. Additional concerns about these drugs include interference with heat dissipation, exacerbation of tachycardia, prolongation of the QT interval, induction of torsade de pointes, and precipitation of dystonic reactions.

Once sedation is accomplished, often no additional therapy is required. Specifically, hypertension and tachycardia usually respond to sedation and volume resuscitation. In the uncommon event that hypertension and or tachycardia persists, the use of a β -adrenergic antagonist or a mixed α - and β -adrenergic antagonists is contraindicated. Again, in both animal models and human reports, these drugs increase lethality and fail to treat the underlying central nervous system excitation.^{12,23,65,184,213} (See Specific Management below.) The resultant unopposed α -adrenergic effect may produce severe and life-threatening hypertension or vasospasm. A direct-acting vasodilator such as nitroglycerin, nicardipine, or an α -adrenergic antagonist (such as phentolamine) may be considered. Other nonspecific therapies for rhabdomyolysis such as intravenous fluid should also be considered.

Decontamination

The majority of patients who present to the hospital following cocaine use will not require gastrointestinal decontamination as the most popular methods of cocaine use are smoking and intravenous and intranasal administration. If the nares contain residual white powder presumed to be cocaine, gentle irrigation with 0.9% sodium chloride solution will help remove adherent material. Less commonly, patients may ingest cocaine unintentionally or in an attempt to conceal evidence during an arrest (body stuffing)^{78,101,135,201} or transport large quantities of drug across international borders (body packing).^{58,63} These patients may require intensive decontamination and possibly surgical removal²³² (Special Considerations: SC5).

Specific Management

End-organ manifestations of vasospasm that do not resolve with sedation, cooling, and volume resuscitation should be treated with vasodilators (such as phentolamine). When possible, direct delivery via intraarterial administration to the affected vascular bed is preferable. Because this approach is not always feasible, systemic therapy is typically indicated. Phentolamine can be dosed intravenously in increments of 1 to 2.5 mg and repeated as necessary until symptoms resolve or systemic hypotension develops.

Acute Coronary Syndrome. A significant amount of animal, in vitro, and in vivo human experimentation has been directed at defining the appropriate approach to a patient with presumed cardiac ischemia or infarction. In some instances, an approach that is similar to the treatment of coronary artery disease is indicated, although there are certain notable exceptions. An overall approach to care is available in the American Heart Association guidelines and a number of reviews.^{3,84,117,143}

High-flow oxygen therapy is clearly indicated as it may help overcome some of the supply–demand mismatch that occurs with coronary insufficiency. Aspirin is likely safe in patients with cocaine associated chest pain and is recommended for routine use.¹⁴³ In addition, administration of morphine is likely to be effective as it relieves cocaine-induced vasoconstriction.¹⁸¹ Morphine also offers the same theoretical benefits of preload reduction and reduction of catecholamine release in response to pain that is thought to be responsible for its usefulness in patients with coronary artery disease.

After these interventions, the treatment of patients with cocaine-associated chest pain begins to deviate from the standard accepted approach to patients with coronary artery disease. Nitroglycerin is clearly beneficial as it reduces cocaine-associated coronary constriction of both normal and diseased vessels and relieves chest pain and associated symptoms.⁸⁰ Interestingly, in several clinical trials of cocaine-associated chest pain, benzodiazepines are at least as effective or superior to nitroglycerin.^{8,92} Although the reasons for this are unclear, possible etiologies include blunting of central catecholamines or direct effects on cardiac benzodiazepine receptors. Either or both drugs can be used in standard dosing (Antidotes in Depth: A23).

Over the past decade, the benefits of β -adrenergic antagonism have been demonstrated in patients with CAD. In contrast, β -adrenergic antagonism increases lethality in cocaine-toxic animals^{23,65} and in humans, exacerbates cocaine-induced coronary vasoconstriction, and produces severe paradoxical hypertension.¹⁸⁴ Mixed alpha and beta adrenergic antagonists do not appear to offer any advantage in the treatment of patients with cocaine associated chest pain. For the treatment of coronary constriction, labetalol is no better than placebo.¹² This is likely due in part to the relative ratios receptor blockade. Intravenous labetalol has a relative $\beta:\alpha$ receptor blockage of 7:1.¹⁷⁴ Carvedilol has a ratio of 2.4:1.¹⁶

Thus, in the setting of cocaine use, β -adrenergic antagonism is absolutely contraindicated. The 2008 American Heart Association Guidelines for the treatment of cocaine-associated chest pain and MI state that use of β -adrenergic antagonists should be avoided in the acute setting.¹⁴³ If, after the measures mentioned previously have been initiated, hypertension or vasospasm is still present and treatment is indicated, phentolamine is preferred based on its demonstrable experimental and clinical results.^{87,117} If tachycardia does not respond to accepted therapies above, then diltiazem can be administered and titrated to effect.¹¹ Prior to the administration of any negative inotrope, it is essential to confirm that the tachycardia is not compensatory for a low cardiac output resulting from global myocardial dysfunction. Noninvasive methods of assessment of cardiac function have been used successfully in patients with cocaine-associated acute coronary syndromes.⁷

There are no data on the use of either unfractionated or low-molecular-weight heparins, glycoprotein IIb/IIIa inhibitors, or clopidogrel. The recent American Heart Association guidelines recommend the administration of unfractionated heparin or low-molecular-weight heparin in patients with cocaine-associated MI.¹⁴³ The decision to use any of these medications should be based on a risk-to-benefit analysis. Consideration should be given to the possibility of underlying atherosclerotic heart disease. When acute thrombosis is likely, thrombolytic therapy should be considered. Mechanistically, cocaine inhibits endogenous thrombolysis through augmentation of the inhibitor of tissue plasminogen activator. Additionally, there is sufficient clinical evidence to support the safety of thrombolytic therapy in patients with cocaine-associated MI.^{80,86} Even though the number of patients treated with thrombolytic therapy is insufficient to demonstrate efficacy in terms of mortality, evidence of revascularization is encouraging. If available, cardiac catheterization with revascularization is preferable to thrombolysis.^{195,198} A high rate of stent thrombosis after MI is reported in cocaine users. Thrombolysis would not be expected to be useful in treating ischemia caused by vasospasm. Due to the high incidence of coexisting atherosclerotic disease and an increased hypercoagulable state in cocaine-associated MI, thrombolysis is an acceptable alternative when catheterization is unavailable. Standard contraindications such as persistent hypertension, aortic dissection, trauma, and altered mental status must be considered prior to thrombolysis.

Dysrhythmias. Most patients present with sinus tachycardia that resolves following sedation, cooling, rehydration, and time to metabolize the drug. Other stable dysrhythmias should be treated similarly and will often spontaneously revert because of the short duration of effect of cocaine. However, cocaine use is associated with atrial, supraventricular, and ventricular dysrhythmias, including torsade de pointes.^{97,118,191} Most notably, wide complex tachycardias result from sodium channel blockade.

When approaching patients with cocaine-associated dysrhythmias, there are several important points to consider. The first is that β -adrenergic antagonism is contraindicated. Furthermore, class 1A and 1C antidysrhythmics are also contraindicated because of their ability to exacerbate cocaine-induced sodium and potassium channel blockade.^{118,226} Additionally, although popular in many advanced cardiac life support dysrhythmia algorithms, the effects of amiodarone are largely unknown in the setting of cocaine toxicity. Because of the lack of data demonstrating a benefit for amiodarone, and because of concerns about its β -adrenergic antagonist effects, the use of this drug cannot be recommended. Finally, although adenosine and synchronized cardioversion may transiently help convert narrow complex tachycardias, if a substantial amount of cocaine is unmetabolized, the patient will likely revert back to the original dysrhythmia as these therapeutic interventions have short durations of effect. Thus for rapid atrial fibrillation and narrow complex reentrant tachycardias, a calcium channel blocker such as diltiazem is preferred. For wide-complex dysrhythmias, a trial of hypertonic sodium bicarbonate has demonstrable usefulness analogous to treating patients with cyclic antidepressant overdose (Antidotes in Depth: A5).^{106,116,163,181,221,226,239,246} When the use of hypertonic sodium bicarbonate fails to treat the dysrhythmia, lidocaine can be used. Although lidocaine blocks sodium channels, its fast-on, fast-off properties allow it to antagonize the effects of cocaine. The benefits and safety of lidocaine were demonstrated in multiple animal models^{64,69,75,81,226,246} and in humans with cocaine-associated MI.^{105,215}

Ischemic Stroke. The safety of thrombolysis in cocaine-associated ischemic stroke is uncertain. Cocaine use can increase the risk of both ischemic stroke and intracerebral hemorrhage. One study found no increase in intracerebral hemorrhage after administration of tissue plasminogen activator in patients who had recently used cocaine, although acute cocaine intoxication was not specifically investigated.¹³⁷

ADULTERANTS

Adulterants are present in illicit drugs for varied reasons, including impure manufacturing processes, increasing drug bulk,

and mimicking or enhancing effects. Historically, cocaine has included inert substances such as starches, sympathomimetic agents and other local anesthetics.²⁷

In 2003, a new adulterant, levamisole, was identified. Levamisole is an antihelminthic immunomodulator. It was withdrawn from the US market in 2000 primarily because of agranulocytosis. By 2009, the US Drug Enforcement Agency estimated that 69% of cocaine contained levamisole.¹²¹ Two primary categories of levamisole toxicity are identified. The first is hematologic effects, including neutropenia and agranulocytosis. The second is dermatologic effects, including vasculitis and purpura. Reexposure to cocaine with levamisole may cause recurrence of these symptoms. A multifocal inflammatory leukoencephalopathy is also reported after use of contaminated cocaine.

DISPOSITION

Patients who present to health care facilities with classic sympathomimetic signs and symptoms that resolve spontaneously in the absence of signs of end-organ damage can be safely discharged after short periods of observation. Once hyperthermia, rhabdomyolysis, or other signs of end-organ damage are evident, hospital admission is usually required. Patients who use cocaine are at increased risk for sudden death likely related in part to dysrhythmias and myocardial ischemia. In one series, patients with cardiac arrest after smoking crack cocaine were younger, more likely to survive, and less likely to have neurologic sequelae than case controls.⁹⁵

For patients with chest pain, a specific management algorithm has been derived based on substantial clinical experience. Those patients with clearly diagnostic or evolving ECGs suggestive of ischemia or infarction, positive cardiac biomarkers, dysrhythmias other than sinus tachycardia, congestive heart failure, or persistent pain require admission. Patients who become pain free and whose ECGs are stable are candidates for discharge if a single cardiac marker obtained at least 8 hours after the onset of chest pain is normal.²²³ The American Heart Association guidelines recommend 9 to 12 hours of observation for low- and intermediate-risk patients with cocaine-associated chest pain.¹⁴³

For all patients, it is essential to provide a referral for detoxification. Repeated cocaine use is the greatest risk factor for future cardiovascular complications.^{88,180,224} Additionally, cocaine use in patients treated for traumatic injury is a risk factor for subsequent death from unintentional injury.

SUMMARY

- A sympathomimetic toxidrome is the typical clinical presentation.
- Life-threatening hyperthermia may occur.
- Treatment of agitation should focus on rapid sedation with a benzodiazepine and cooling if indicated.
- Myocardial infarction and dysrhythmias occur via diverse mechanisms.
- Both ischemic and hemorrhagic stroke may occur.

SC5 SPECIAL CONSIDERATIONS

Internal Concealment of Xenobiotics

Jane M. Prosser

Internal concealment of illicit xenobiotics is a significant concern for local and international police efforts as well as medical and public health practitioners. There are two distinct categories of concealment colloquially known as “body stuffers” and “body packers.” The term body stuffer refers to individuals who hide xenobiotics in a body cavity or ingest them in an attempt to hide evidence from law enforcement officers. The xenobiotics are ingested in an unplanned manner and are often poorly wrapped. The term body packer refers to individuals who conceal xenobiotics, typically in large quantities, in a premeditated fashion almost exclusively for the purposes of international smuggling.

BODY PACKERS

Internal concealment of xenobiotics for the purpose of smuggling was first reported in Canada in 1973. A 21 year-old man presented with a small bowel obstruction as a result of swallowing a condom filled with hashish. He had swallowed the condom in order to transport it into Canada after a trip to Lebanon.¹⁴ Internal xenobiotic smuggling has become a worldwide problem as increased surveillance at international borders has made conventional transportation of illegal xenobiotics more difficult. Improved detection of smugglers has increased the number of patients brought to the attention of health care providers. Pregnant women and children as young as 6 years of age have been used as body packers.^{3,6,9}

Airline and airport personnel are trained to identify people who may be xenobiotic couriers. Suspicious behavior includes not eating or drinking on the airplane, abnormal behavior while going through customs, and overt signs of xenobiotic toxicity.^{68,77}

Composition of Packages

Body packers typically swallow large numbers of well prepared packages, each filled with substantial amounts of xenobiotic. Packets may also be concealed by insertion into the vagina and rectum.^{15,82} The most frequently smuggled cargo is either heroin or cocaine, but other xenobiotics have been reported (Table SC5–1). Body packers often swallow 50 to 100 packages, and ingestion of as many as 500 has been reported.⁸³ Each package typically contains from 0.5 to 10 g of xenobiotic. Therefore, one person may carry as much as 1.5 kg of drug.⁷⁵ Lethal doses of cocaine and heroin are difficult to determine based in part on sparse data and on widely variable purity. For reference, death from cocaine toxicity is reported after ingestion of as little as 2 to 3 g.⁶³ As such, each packet should be considered to contain a potentially lethal dose.

TABLE SC5–1. Xenobiotics Associated with Internal Concealment	
Substances reported in body stuffer ingestion	
Cannabis ⁷⁶	
Cocaine hydrochloride ⁶⁴	
Crack cocaine ⁶⁴	
Heroin ⁴¹	
Methamphetamine ³²	
Prescription drugs ⁷⁶⁵	
Substances reported in body packer ingestion	
Cannabis ^a	
Cocaine powder and liquid ¹³	
Hashish ^b and hashish oil ⁵³	
Heroin ²⁴	
Methamphetamine ^a	

Methylenedioxymethamphetamine (ecstasy)^c

Oxycodone³

^aLow VHS, Dillon EK: Agony of the ecstasy: report of five cases of MDMA smuggling. *Australas Radiol.* 2005;49:400–403. ^bPamilo M, Suoranta H, Suramo I: Narcotic smuggling and radiography of the gastrointestinal tract. *Acta Radiol Diagn.* 1986;27:213–216. ^cTakekawa K, Ohmori T, Kido A, Oya ML: Methamphetamine body packer: acute poisoning death due to massive leaking of methamphetamine. *J Forensic Sci.* 2007;52:1219–1222.

A number of materials have been used for xenobiotic packaging. Some, like latex, are used as wrappers. Others such as carbon paper and aluminum foil are used to change the radiodensity and decrease the likelihood of detection with diagnostic and forensic imaging studies. Packages have been made using plastic bags, plastic wrap, condoms, finger cots, balloons, cellophane, wax, tape, rubber gloves, surgical ligatures, paraffin, and fiberglass.^{5,24,31,52,60}

Initial reports suggested a high rate of complications due to packaging failure.⁵² More recently, however, advances in the technology of packet construction have decreased rates of rupture.⁶⁰ A typical packet in current use is composed of a core of compacted xenobiotic covered by several layers of latex and encased in an outer wax coating.⁷⁷ Recently, the transport of xenobiotic in liquid form has been reported.

Important historical details include the number and contents of packets, the type of wrapping, time of ingestion, and any associated symptoms. Body packers, as well as those financing and receiving the packages, generally know exactly how many packets are being carried. However, the individual may be reluctant to give an accurate clinical history to the health care provider or legal authorities.

Bioavailability

The oral bioavailability of cocaine hydrochloride is approximately 30% to 40%, which is similar to intranasal administration.^{19,86} Rectal and vaginal bioavailability of cocaine hydrochloride and the oral, rectal, and vaginal bioavailability of crack cocaine have not been studied.

Oral exposure to heroin results in rapid first pass metabolism to morphine²⁶ and can be considered a morphine prodrug.^{19,38} The peak concentrations after 10 mg of oral heroin are similar to those expected from 10 mg of oral morphine.³ The rectal bioavailability of morphine has a 1:1 ratio with oral administration. Although heroin is rectally bioavailable,⁶⁷ one study examining the bioavailability after rectal suppository administration in two opioid dependent patients found it to be approximately 50% less than the oral bioavailability.²⁸

Clinical Manifestations

Body packers undergoing medical examination may be asymptomatic or may have clinical manifestations consistent with either xenobiotic toxicity or mechanical obstruction. Physical examination should be thorough, with a focus on findings related to these problems (**Chaps. 38 and 78**).

The packets may be too large to pass, and obstruction can occur at any point in the gastrointestinal tract. Individuals carrying packets containing opioids appear to be at higher risk of gastrointestinal obstruction, even with intact packets.²⁵ The reason for this is unclear, but may be related to microperforation of the package or contamination of the outside of the package during manufacture, resulting in opioid induced gastrointestinal stasis. Patients with a history of abdominal surgery may also be at increased risk of obstruction.^{12,36} Gastrointestinal perforation and peritonitis can result if the obstruction is untreated.¹² Dysphagia,⁷ esophageal perforation and mediastinitis,^{36,39} gastric ulcers,⁵⁶ gastric hemorrhage,^{16,36} esophageal obstruction,⁴⁴ hematochezia,⁷⁹ incarcerated hernias,⁷⁴ uterine ischemia,⁷ and septic shock²⁵ have resulted following packet rupture.

Laboratory Evaluation

Drug screening results may be difficult to interpret. Although generally, a positive result should raise concern for a ruptured packet, positive results may also be due to external contamination of the packet during preparation from a microperforation or from prior utilization. Thus, patients with packets that appear externally intact may have a positive urine drug screen.^{25,53} The rate of positive screens in asymptomatic patients may be as great as 52% to 72%.^{13,16} Screening typically correlates closely with the drug carried,²⁴ but it may be misleading as patients transporting any xenobiotic may ingest opioids for the purpose of slowing gastrointestinal transit time.⁵⁷ Additionally, patients may be carrying a combination of xenobiotics, known as “double breasting.”²⁵

A subsequent urine drug screen may be particularly useful in the setting of a patient with an initially negative screen. A screen that later becomes positive suggests a ruptured packet and is an indication for very close monitoring. This is of particular concern in the setting of a cocaine body packer when a change from a negative to a positive screen might indicate the potential for a precipitous decline.

Radiographic Evaluation

All suspected body packers should undergo radiographic evaluation. Plain abdominal radiographs have a sensitivity of 75% to 95%, but this varies based on the number of packets and their methodology of construction.^{5,52,81} Several authors suggest increased sensitivity with supine abdominal films.^{50,83} Packets can be visualized as multiple radiodense foreign bodies (**Figs. 5-8 A–C**). The “double condom sign” is a lucent ring surrounding the packet and results from air trapped in between layered wrappings.⁶¹ The “rosettelike” sign results from the air trapped in the knot when the condom or balloon is tied.⁷¹ Caution must be used when interpreting plain radiographic studies. In one series, 19% of patients had false-negative radiographs, with one patient subsequently passing 135 packets.⁵² False-positive results have also been reported due to constipation,⁴³ intraabdominal calcifications,⁷⁸ and bladder stones.⁸⁷ Contrast enhancement may increase the sensitivity of plain radiography.^{23,35,50}

Computed tomography (CT) scanning has a higher sensitivity than plain radiography,^{30,46} with sensitivities reported to range from 96% to 100%.^{1,22,88} Although likely to identify patients with multiple packets, a false-negative contrast CT scan following whole bowel irrigation was reported in a body packer who subsequently passed a single packet per rectum.²⁹ Retrospective review of the CT could not identify the packet. One study found a difference in Hounsfield units between packets containing cocaine (–219 HU) and heroin (–520 HU), suggesting that CT scanning can also potentially distinguish between package contents. However, other authors report a lack of utility of this measurement due to variation in drug formulation, compression, and packing materials⁸⁵.

Ultrasonography may be another useful screening tool to reduce radiation exposure, particularly for evaluation of women of childbearing age. However, its utility has only been evaluated in a few small case series.^{34,54} In one series of patients arrested on suspicion of body packing at an international airport, ultrasound examination correctly identified 40 of 42 body packers with positive plain radiographs. The two false-negative results occurred when packets were located low in the rectum.⁵⁴ More investigation is needed to determine the sensitivity and specificity of ultrasound for use in these patients.

Magnetic resonance imaging (MRI) is not likely to provide any additional information when evaluating the gastrointestinal tract. The utility of MRI may be limited for examining the bowel because of the presence of air and normal peristalsis.³³

Pregnant women may be targeted to become body packers due to hesitation from customs officials and health care providers to obtain radiographs. However, the average radiation dose of 100 millirads from an abdominal radiograph is much less than the threshold thought to induce fetal malformations. Consideration should also be given to the use of ultrasonography in this situation.⁹ In all patients, risk of exposure to radiation must be weighed against the risks of undiagnosed internal concealment of xenobiotics.

Management

Gastrointestinal decontamination is a vital element in the management of body packers. Initially, surgical intervention was thought to be necessary in all body packers secondary to perceived high rates of toxicity and death.^{21,73} The incidence of life-threatening complications has decreased due in part to both better packaging^{52,60} and to increased rates of detection of asymptomatic carriers. Currently, a more conservative nonsurgical approach is suggested for asymptomatic patients⁷⁷ and is supported by a several large series (**Fig. SC5–1**).^{4,5,13,52,68,81,83}

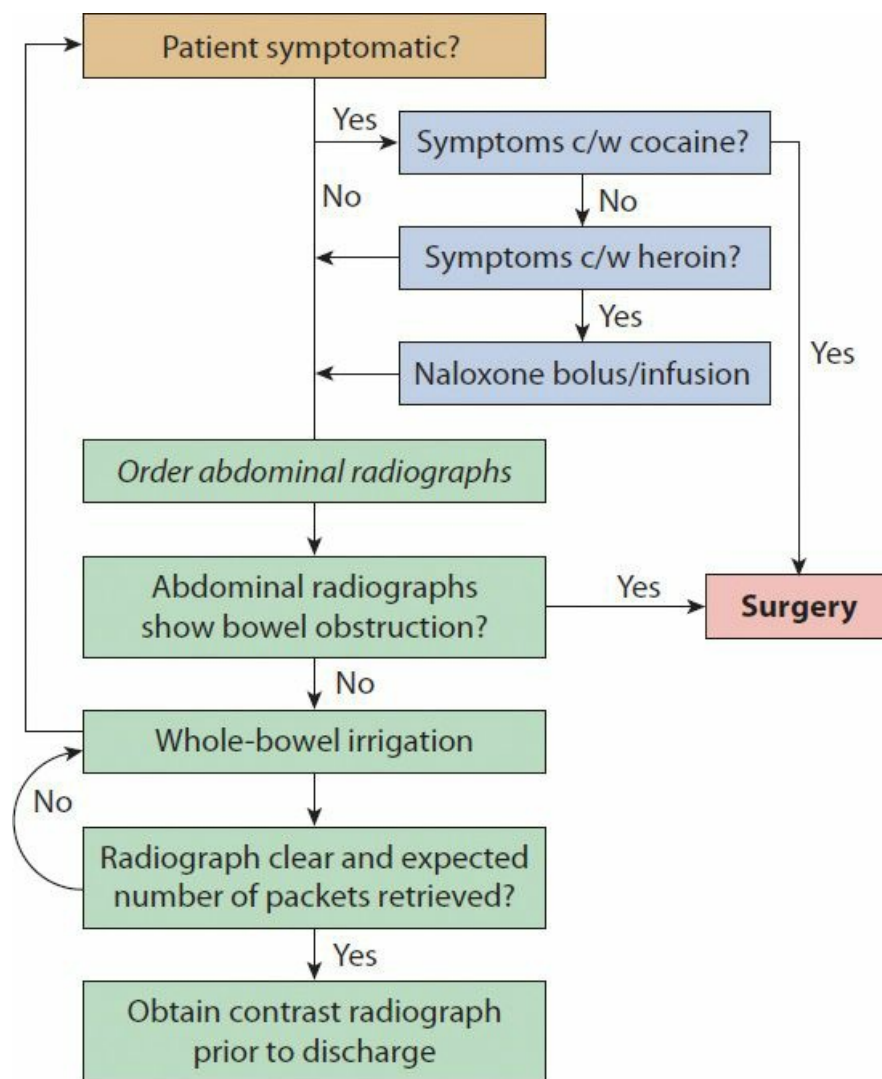

FIGURE SC5-1 Algorithm for managing cocaine or heroin body packers.

Treatment with activated charcoal (AC) is frequently suggested on the basis that cocaine and heroin are both well adsorbed to AC.⁴⁹ There are no data showing an actual benefit, and the large doses needed to adsorb the many grams of xenobiotic released during packet rupture may make AC impractical for use. Furthermore, AC may be detrimental if contamination of the peritoneal cavity occurs after gastrointestinal rupture or during surgery or if it obscures visualization should endoscopy become indicated. The risks and benefits must be weighed in each patient. AC is of questionable value in cocaine packers given the higher risk of the need for surgical intervention. Also, it is not likely to improve the outcome of symptomatic heroin body packers, as these patients can be successfully managed with opioid antagonists and mechanical ventilation. Therefore, the administration of AC is not likely to be of benefit.

The utility of whole bowel irrigation (WBI) to enhance elimination is generally accepted but has not been rigorously evaluated. There is a theoretical concern that polyethylene glycol could increase the water solubility of heroin should rupture occur,⁸¹ and that it may decrease the adsorption of cocaine to AC should AC be given.⁴⁹ Given the lack of in vitro data to support these risks,¹⁸ and its generally accepted benefit, WBI is recommended to decrease intestinal transit time (Antidotes in Depth: A2). Orogastric lavage is not indicated as packets are too large to fit through holes in the lavage tube.

Cathartics are sometimes recommended for gastrointestinal decontamination. Although oil-based cathartics were frequently used in the past,^{5,51} a non-oil-based medication such as magnesium citrate is preferred. Paraffin oil may actually dissolve some packet wrappers, potentially resulting in drug toxicity.⁸⁴ Safe use of pro-motility xenobiotics, such as metoclopramide and erythromycin, is also reported.⁸⁰ Enemas and manual disimpaction should be avoided or used with great caution, as packet rupture may occur.^{40,47}

Treatment of symptomatic patients depends on the nature of the xenobiotic ingested. Patients manifesting opioid toxicity should be treated with the opioid antagonist naloxone and mechanical ventilation if necessary. Opioid antagonists also improve gastrointestinal motility (Antidotes in Depth: A4). Surgical decontamination is generally not indicated for opioid poisoning, as optimal medical therapy should be adequate.

Rupture of a cocaine packet, however, is a life-threatening emergency that requires aggressive medical and surgical therapy (Chap. 78). Benzodiazepines or other sedatives such as propofol may be used as a temporizing measure, but surgical decontamination should be performed emergently in body packers with any sign of cocaine or amphetamine toxicity. Indications for surgery include, but are not limited to, hypertension, tachycardia, agitation or other alteration in

mental status, myocardial ischemia, bowel ischemia, seizures, respiratory distress, and the transition of a urine drug screen from negative to positive.

Surgical removal of the packets is the therapy of choice in the case of cocaine toxicity or mechanical obstruction, but it may not be definitive.^{31,59,70} In one series, 6 of 70 patients were found to have retained packets postoperatively.¹² Also, emergent surgical removal is associated with a high rate of postoperative infection and fascial dehiscence for reasons that are not well understood.^{11,12,70} Endoscopy^{66,69,81} and proctoscopy²⁷ have been used successfully for removal of packets in several cases. However, caution must be used as attempted endoscopic removal can cause packet rupture and resultant toxicity.⁷³

It is essential to ensure the passage of all packets prior to discharging a patient from medical care. Packets may remain even in patients with clear rectal effluent following WBI.³⁵ After negative plain radiographs are obtained, a confirmatory study should be done using contrast plain radiography or CT scan. However these modalities do not have 100% sensitivity and retained packets may be missed.²⁹ It is therefore recommended that patients be observed for twenty-four hours after the passage of three packet free stools⁵ and a negative confirmatory radiograph or CT scan (**Fig. SC5–1**). Complete gastrointestinal decontamination must be ensured before releasing the patient from close medical observation.

BODY STUFFERS

Body stuffers usually present to health care when they are taken into custody by law enforcement officers. Typically, the person has hastily ingested the xenobiotic or inserted it into the rectum or vagina to hide the evidence from the police. Since the person was not planning to conceal the xenobiotic, the xenobiotic may be unwrapped, as in the case of crack cocaine “rocks,”⁵⁵ or poorly wrapped in materials intended for distribution.

Pertinent historical information includes time of ingestion, xenobiotic, amount ingested, packaging, and symptoms consistent with xenobiotic ingestion. Unfortunately, an accurate history is often difficult to obtain. Patients who are recent arrestees may anticipate a secondary gain of delayed incarceration by reporting the ingestion of drugs; alternatively, the individuals may deny ingestion to avoid prosecution. Complicating the clinical picture is the possibility that law enforcement officers may assume internal concealment of illicit substances when they are unable to find a substance after the arrest.

Composition of Packages

Since xenobiotics are typically transported locally in plastic bags, condoms,⁷² balloons,⁸ glassine envelopes, aluminum foil,⁶⁵ or crack vials,³⁵ these are the most frequently reported wrappers. Reported amounts vary from one dose to up to 30 packages of unspecified dose.⁴¹ Cocaine, either in crack rocks or the hydrochloride salt form are most commonly ingested,⁶⁴ but other xenobiotics are also reported (**Table SC5–1**). Typically, the xenobiotics are ingested although other routes of exposure include the external auditory canal, rectum, and vagina.^{45,48,76}

The importance of obtaining a precise history related to packaging material is highlighted by an in vitro study examining the effects of packet construction, medium used for dissolution, and pH on release of cocaine from drug packets. Cocaine was released almost immediately from paper packaging and least readily from condoms. Cellophane packing led to intermediate serum concentrations compared to paper and condom wrapper. When packets were double or triple wrapped in cellophane, decreased concentrations were noted. All packets released more xenobiotic in an acidic medium.²

Clinical Manifestations

After oral ingestion of drug packets or crack rocks, toxicity is most frequently absent or mild.^{41,42} However, although most case series report low rates of complications, both significant toxicity and death occur.^{20,37,42,57} The time of onset of symptoms in body stuffers is typically within several hours.^{1,41,42} Following the ingestion of cocaine in crack vials, onset of symptoms may be delayed by 3 to 4 hours.³⁵

Most body stuffers reported in the literature had symptom onset, when present, within 6 hours after ingestion. Delayed symptoms after 6 hours can occur; however, in nearly all reported cases, these patients displayed symptoms at the time of medical contact. Two exceptions are noted in the literature. A 50 year-old woman reported ingesting xenobiotics at the time of incarceration. Seven hours later, a prison physician noted normal pulse and mental status, and she was placed in her cell to be observed by staff members every half hour. Prison staff documentation noted that she was “correct” and sat up 30 minutes before being found dead in the cell 11 hours after the time of ingestion. Postmortem examination revealed an open cocaine packet in the intestine.⁵⁸ A patient who placed methamphetamine in a plastic bag with a small hole in an attempt to create a sustained-release mechanism presented for care of abdominal pain 10 hours later. This patient remained without symptoms of methamphetamine intoxication until 42 hours after ingestion.³²

Laboratory Evaluation

Laboratory xenobiotic testing may be difficult to interpret in body stuffers, as these patients are often habitual substance users. Thus, a positive drug screen could be equally indicative of either prior use or current toxicity or both. Likewise, a negative result does not exclude recent ingestion or leaking packages. One study of 50 suspected body stuffers found that urine drug screening correctly classified the presence or absence of packets only 57% of the time.⁵¹ Several authors report toxicity or death occurring in the presence of a negative urine screen despite symptoms consistent with packet contents.^{25,32} One explanation is that patients may die of drug toxicity before substantial urinary excretion occurs.

Radiographic Evaluation

Although detection of stuffed xenobiotics may be possible by diagnostic imaging studies, the sensitivity is very poor.^{17,41,51} Plastic bags, crack vials, and staples (enclosing plastic bags) are rarely visualized.⁴¹ In one series of patients with crack vial ingestions, only 2 of 23 of abdominal radiographs were positive³⁵ in patients who subsequently passed vials. In two other series of cocaine body stuffers, all plain radiographs were negative.^{42,72} Several authors suggest that radiographic detection can be increased with oral contrast, although its utility has not been established.^{10,42} CT scanning may identify some packets missed on plain radiographs, but the sensitivity has not been investigated and missed packets have been reported with CT scanners as well.¹⁷ Therefore, CT scanning is not likely to be clinically useful in these patients.

Management

Body stuffers who exhibit xenobiotic toxicity should be managed according to standard principles for managing that xenobiotic or suspected xenobiotic ([Chaps. 38 and 78](#)).

Patients with gastrointestinal complaints should be evaluated for ileus or obstruction. Removal of packets has been performed by endoscopy,^{10,41,62} but is useful only for a small number of packets, as each package requires an additional passage of the endoscope. Endoscopy should be used with extreme caution as it may cause packet rupture with subsequent toxicity or aspiration of the packet with airway obstruction.⁷³ Bronchoscopic removal of pieces of a balloon wrapping in the airway was successful in one patient after attempted orogastric lavage led to balloon aspiration.⁸ Use of colonoscopy⁶⁸ is also reported but carries a risk of rupture similar to that associated with upper endoscopy. The need for surgical intervention has been reported in only one case. This patient presented with a complaint of epigastric pain 3 days after ingesting a large plastic bag filled with 15 to 20 smaller bags of cocaine. He showed no signs of cocaine toxicity but required surgical removal, as the bag was still retained in the stomach 4 days postingestion.¹⁷

Management of asymptomatic body stuffers has not been rigorously evaluated. Treatment with AC and WBI was often advocated for high-risk patients. Although these methods have not been proven to reduce morbidity or mortality, they offer theoretical benefits.^{35,41,42,72} AC may reduce the absorption of liberated xenobiotic as both heroin and cocaine are well adsorbed to AC. WBI may reduce intestinal transit time, leading to earlier passage of packets. However, it is unlikely to offer any clinical benefits, unless life-threatening amounts of xenobiotic (in packages) are ingested.

A therapeutic end point has not been established in part because packages are often not recovered from body stuffers. Review of more than 1000 published cases of body stuffers, involving a variety of packaging methods, reveals only a few cases in which onset of toxicity occurred more than 6 hours after ingestion (when the time of ingestion is reported) and was not present at the time of initial medical evaluation. There are several cases reported when onset of symptoms occurred between 8 and 10 hours postingestion of “crack rocks”; however, in all of these cases (except in the two cases noted above), symptoms were present at the time of initial health care contact.^{10,62}

Management strategies should consider the potential dose ingested, time since ingestion, and therapy administered. Because the vast majority of patients remain asymptomatic or develop symptoms shortly after medical contact, it is reasonable to observe asymptomatic patients given AC for 6 hours. Because rare patients may have more delayed presentations, patients who have ingested large, potentially lethal doses should be observed for longer periods of time in a closely monitored setting. Multiple stools devoid of packages or a lack of symptoms after 24 hours are reasonable end points for monitoring these patients.

LEGAL PRINCIPLES

Because clinical errors have the potential for life-threatening consequences, it is essential to evaluate patients within the context of their unique medical, social, ethical, and legal settings. It is important to remember there may be significant motivation to deny ingestion altogether or conceivably secondary gain from overreporting the dose in order to delay incarceration. Often, patients will refuse medical care either as an assertion of innocence or over concerns that evidence produced might be incriminatory.

In the United States, patients may refuse care if they are competent to do so. This includes body stuffers and body

packers who are under arrest. Patients with decisional capacity cannot be forced to take AC, WBI, any other form of therapy or diagnostic procedure. If in police custody, however, the individual may be kept in the hospital for an extended observation period. This strategy maintains the patient's medical autonomy as well as ensures clinical stability. If signs of life-threatening toxicity subsequently develop, the patient will most likely have lost decisional capacity, and therapy and management can proceed as medically necessary.

If a body packer who is not in legal custody presents for medical care, physicians may face an ethical dilemma. Calling the authorities is a violation of the patient's right to confidentiality. However, possession of large amounts of drugs may theoretically endanger the hospital staff as criminal elements expect drug delivery. Consultation with hospital legal counsel, risk management, and the ethics committee may be helpful in this situation ([Chap. 141](#)).

SUMMARY

- Patients with intestinal concealment of xenobiotic present a diagnostic and therapeutic challenge.
- History, laboratory, and radiologic studies must be interpreted with caution.
- Management strategies should focus on the xenobiotic ingested and be tailored to the needs of each individual patient.
- Gastrointestinal decontamination is the most important consideration in asymptomatic patients.
- A complex patient physician relationship is common and must be effectively transformed into a trusting relationship to ensure reliable and high quality care.

A23 ANTIDOTES IN DEPTH

Benzodiazepines

Robert S. Hoffman, Lewis S. Nelson, and Mary Ann Howland

Benzodiazepines are used as first-line anticonvulsants for virtually all xenobiotic induced seizures; as sedatives of choice for most forms of xenobiotic induced agitation; as muscle relaxants for diverse disorders such as serotonin toxicity, neuroleptic malignant syndrome, and poisoning from strychnine or black widow spider envenomation; and as sedatives for withdrawal from ethanol, γ -hydroxybutyric acid, and other sedatives. Additional distinct indications for benzodiazepines can be found in overdose from chloroquine and possibly other quinine derived antimalarials, and in patients with cocaine associated myocardial ischemia and infarction. This Antidotes in Depth provides a summary of the clinical pharmacology of benzodiazepines in order to provide the reader with the background necessary to administer these drugs as safely and effectively as possible.

HISTORY

Most ancient texts make reference to the use of some plant or natural substance for sedation. By the mid to late 1800s, many of the natural sedatives were replaced by alcohol and chloral hydrate.¹⁷ The search for better sedatives with fewer side effects led to the development of barbiturates in the early 1900s followed by numerous others such as meprobamate, glutethimide, and ethchlorvynol (Chap. 74). Since the introduction of chlordiazepoxide in 1960,⁷⁷ benzodiazepines have gained acceptance as safe and effective drugs for a large variety of clinical indications. Over the intervening years, the number of benzodiazepines has increased, with each new drug demonstrating unique and complex pharmacology.

CHEMISTRY

All benzodiazepines share a common chemical structure, shown in Fig. A23–1. This structure links a benzene ring with a diazepine ring and gives rise to the name used to describe the drug class. The additional phenyl ring is present in all clinically important benzodiazepines and serves as a site of substitution that modulates certain pharmacologic characteristics. The pyrazolopyrimidines (zolpidem, zopiclone, and zaleplon) lack the typical benzodiazepine structure but have similar pharmacologic effects.²⁸ Since these pharmaceuticals are largely unstudied for the antidotal indications described above, they are not discussed in depth here. A discussion of the manifestations and treatment of overdose of benzodiazepines and similar xenobiotics can be found in Chap. 74.

FIGURE A23–1. Generic structure of benzodiazepines.

γ -AMINOBUTYRIC ACID TYPE A RECEPTORS

Benzodiazepines target the γ -aminobutyric acid type A (GABA_A) receptor, which is a ligand-gated chloride channel, but have no appreciable binding to GABA_B. When GABA is present on its GABA_A receptor, benzodiazepines increase the frequency of channel opening, resulting in enhanced flow of negatively charged chloride ions into the cell with resultant hyperpolarization.⁸³ However, in the absence of GABA, benzodiazepines have no effect on chloride conductance. The

GABA_A receptor is assembled from five subunits that span the cell membrane in a circular fashion to create the chloride channel.⁵⁸ These subunits are coded as α , β , γ , δ , ϵ , θ , λ or ρ , and at least 19 isoforms of these subunits (such as α_{1-5}) are identified.¹³ If the isoforms of the known subunits could assemble randomly, several hundred thousand possible configurations of the GABA_A receptor would be possible.⁸⁵ However, it appears that a minimum of at least one α , one β , and either one γ or one δ subunit are required to form a functional chloride channel,⁸⁹ and as a result the actual number of configurations is limited. The most common configuration consists of one α , two β , and two γ isoforms.^{85,89}

BENZODIAZEPINE RECEPTORS

Rapidly evolving neuroscience has resulted in an exponential expansion in the understanding of benzodiazepine receptors. As a result multiple, potentially confusing nomenclatures have developed.

Central

The term “central benzodiazepine receptors” is used to refer to benzodiazepine binding sites on GABAergic neurons of the nervous system. Although benzodiazepine binding to the GABA_A receptor cannot occur unless at least one γ subunit is present,¹⁸ the actual site of benzodiazepine binding is located at the interface of an α and a γ subunit; most commonly an α_1 and a γ_2 subunit.^{13,85} Since most receptors only contain a single α subunit, only one benzodiazepine binding site usually exists on each GABA_A receptor. Anatomical variations in the α isoforms produce two common patterns of expression that account for some of the clinical variations between benzodiazepines and the pyrazolopyrimidines mentioned earlier. In older nomenclature, benzodiazepine type 1 (BZ₁) receptors were also called β_1 receptors. They have a predominance of the α_1 isoform, are located in the sensory and motor areas of the brain, and mediate sedative and hypnotic effects. Benzodiazepine type 2 (BZ₂) receptors were also called β_2 receptors. They have a predominance of the α_2 , α_3 , or α_5 isoforms, are located in the subcortical and limbic areas of the brain, and mediate anxiolytic and anticonvulsant effects.⁵⁷ Most typical benzodiazepines have substantial affinity for the α_1 , α_2 , α_3 , and α_5 isoforms, which explains their combined sedative-hypnotic, anxiolytic, and anticonvulsant effects. In contrast, the pyrazolopyrimidines (such as zolpidem) have high affinity for α_1 , intermediate affinity for α_2 and α_3 , and low affinity for α_5 isoforms, which explains their lack of anticonvulsant effect.^{28,59} The α_4 confers resistance to benzodiazepines. This older nomenclature (BZ and β receptors) is now simplified with GABA_A receptors classified as having high, low, or intermediate affinity benzodiazepine binding sites.⁷⁴

On the opposite side of the α isoform where the benzodiazepine receptor is located is an α - β interface. This interface holds the location of a binding site for neurosteroids (Fig. A23–2).³⁸ These neurosteroids are potent modulators of GABA_A receptor function and are important products of the tryptophan-rich sensory protein receptor (peripheral benzodiazepine receptor) stimulation (see below).

FIGURE A23–2. The γ -aminobutyric acid type A (GABA_A) chloride (Cl[−]) channel. The figure demonstrates a typical configuration of the GABA_A Cl[−] channel, which consists of two α , two β , and one γ isoforms. The benzodiazepine (BZD) receptor is located between an α and a γ subunit. Neurosteroid binding at the opposite side of the α isoform is a positive allosteric modulator.

Peripheral Tryptophan-Rich Sensory Protein

The term “peripheral benzodiazepine receptor” (PBR) was originally used in the 1970s to define any benzodiazepine binding sites outside of the nervous system.¹¹ Since these PBRs were subsequently identified in most tissues, including the central nervous system, the term is best applied to binding sites not located on GABAergic neurons. Other names for PBRs included BZ₃ or β_3 receptors to distinguish them from the “central receptors” described above.⁴⁷ However, numerous nonbenzodiazepines have high-affinity binding for these receptors, and their structure and function are so dissimilar from GABA_A-associated benzodiazepine binding sites that other names such as translocator protein (18 kDa), mitochondrial translocator protein (18 kDa), nuclear translocator protein (18 kDa), were appropriate.^{68,84,90} The most recent conventions have adopted the term tryptophan-rich sensory protein (TSPO) as this refers to its gene and denotes it as a tryptophan-rich sensory protein.²⁴ Although the term PBR remains attractive, for simplicity and consistency, the current term TSPO will be used in remainder of this discussion.

The TSPO participates in a heterotrimer structure that is composed of an isoquinoline binding protein, which is the actual receptor (TSPO); a voltage-dependent anion channel (VDAC); and an adenine nucleotide transporter (ANT).⁶⁸ Although the actual function of each subunit is not well appreciated, the minimal functional unit is the TSPO (18 kDa protein).⁴⁵ Sequencing of TSPOs demonstrates that they are highly conserved in nature, with DNA from bacteria and fungi having a nearly 50% homology of the isoquinoline binding domain with human DNA.^{24,27} Homology among mammals exceeds 75%.²⁷ These findings suggest that the PBRs perform a “housekeeping function,” that is, they are involved in a process or processes that are essential for life. In higher life forms, TSPOs can be found primarily in the brain, adrenal glands, heart, and kidney. The TSPO protein and the VDAC span the outer mitochondrial membrane, while the ANT bridges the outer and inner membranes (Fig. A23–3). TSPOs are implicated in cholesterol and protoporphyrin transport required for the synthesis of neurosteroids, heme, and bile salts; ischemia and reperfusion; regulation of calcium channels; mitochondrial respiration; apoptosis; microglial activation; and the immune response.^{27,68,84} More recently, TSPO ligands have been investigated as potential targets for a variety of disorders including anxiety, cancer, ischemia, and others.^{15,19,26,41,42,63,64,67,69,75,80,91} It is hypothesized that TSPO has two major roles: opening of the mitochondrial permeability transition pore (MPTP) leading to calcium influx and apoptosis,^{7,23,26,52} and, as noted above, in synthesis of neurosteroids that modulate GABA_A function.^{67,75}

FIGURE A23–3. The “peripheral benzodiazepine receptor” has three main components: the tryptophan-rich sensory protein (TSPO; 18 kDa translocator protein), a voltage-dependent anion channel (VDAC), and an adenine nucleotide transporter (ANT), which are shown on the mitochondrial membrane. Stimulation of the TSPO can trigger influx of Ca²⁺ or cholesterol across the mitochondrial membrane. SCC = side chain cleavage; MPTP = mitochondrial permeability transition pore.

PHARMACOKINETICS AND PHARMACODYNAMICS

Benzodiazepines are usually administered to treat seizures, psychomotor agitation, or sedative-hypnotic withdrawal. Since these disorders often represent life-threatening emergencies, the initial approach to treatment involves the use of parenteral drugs. Parenteral therapy provides guaranteed absorption with a relatively rapid onset of action. As such, this Antidotes in Depth focuses on the most commonly used parenteral benzodiazepines: diazepam, lorazepam, and midazolam. Clinically important pharmacologic parameters of these three drugs are listed in [Table A23–1](#). Of note, since the existing literature is insufficient to absolutely differentiate individual roles for specific benzodiazepines in particular disorders, these three drugs are often used interchangeably for a variety of indications based on availability within the hospital and regional historic preferences. Only through an understanding of the pharmacology can the clinician select the optimal drug, dose, route, and interval to ensure adequate response and limit adverse reactions. As discussed below, it is important to note that the onset and peak effects of sedative and anticonvulsant activity are distinctly different for each drug and among drugs, so pharmacodynamic data are an important adjunct to the interpretation of pharmacokinetic data.

TABLE A23–1. Pharmacologic Properties of Select Benzodiazepines

Parameter	Diazepam	Midazolam	Lorazepam
Lipid solubility (LogD; octanol/water at pH 7)	3.86	3.68	2.48
Volume of distribution (healthy adults) (L/kg)	0.89 ± 0.18	0.80 ± 0.19	1.28 ± 0.34
Protein binding (%)	97–99	96	85
Hepatic metabolism	Phase 1	Phase 1	Phase 2
Active metabolites	Yes (desmethyl-diazepam and others)	Yes: α-hydroxymidazolam (10% of parent, but accumulates with chronic dosing)	No
Average dose (mg) in 70 kg adult ^a			
Sedation	10 mg IV over 2 minutes Wait 2 minutes before redosing	2 mg IV over >2 minutes (not >1.5 mg in elderly or debilitated patients and over >2 minutes) Wait 2 minutes before titrating	2 mg IV over one minute (dilute with equal volume of NS or D ₅ W prior to injection) Wait 15 minutes before redosing
Status epilepticus (initial dose)	10 mg IV	10 mg IM	4 mg IV
Diluent	Alcohol 10% Benzyl alcohol 1.5% Propylene glycol 40%	Benzyl alcohol 1.0% Sodium edetate 1%	Benzyl alcohol 2% Propylene glycol 80%
Available	5 mg/mL Rectal gel 5 mg/mL	1 mg/mL 5 mg/mL	2 mg/mL 4 mg/mL

^aAvoid intra-arterial administration (since severe spasm may occur with resulting ischemia or gangrene). Also avoid extravasation.

D₅W = 5% dextrose in water; IV = intravenous; NS = 0.9% NaCl.

Intravenous administration guarantees complete and immediate absorption. When intravenous access is unavailable, intramuscular lorazepam or midazolam should be considered as they both have good absorptive profiles.^{33,39,40,43,56,78,88} Midazolam may offer added benefits as its role in synthesis of neurosteroids is experimentally defined.⁸¹ In contrast, the absorption following intramuscular diazepam is best described as slow, incomplete, erratic, and dependent on the site of administration and the skill of the person administering it.^{20,21,39,44,86} Intramuscular injection of diazepam should therefore not be considered unless no other alternatives exist.

Other routes of administration are used for rapid drug delivery when intravenous access is not available. For example, and especially in children, intranasal and rectal administration can be considered. When rectal diazepam was compared with intravenous diazepam in children with seizures, the peak concentration was more variable and was delayed by about 20 minutes.⁶⁶ Additionally, failure rates are higher when rectal diazepam is compared with intravenous diazepam.^{66,71} Similarly, although midazolam is more rapidly absorbed than diazepam following both nasal and rectal administration, the kinetic profile of nasal or rectal midazolam is still inferior to intravenous administration of either diazepam or midazolam.^{35,55,71} Recent evidence has supported a role for intramuscular midazolam for seizures and agitation.^{43,56,78}

Once absorbed, benzodiazepines must distribute into the central nervous system in order to produce their sedative and anticonvulsant effects. The differences among individual drugs can be evaluated in terms of their pharmacokinetics, such as cerebral drug concentrations, or pharmacodynamics, such as changes in either consciousness or electroencephalographic (EEG) findings. A cat model assessed cerebrospinal fluid (CSF) concentrations of benzodiazepines following intravenous administration along with their effects on the EEG.⁵ Diazepam, midazolam, and lorazepam all appeared rapidly in the CSF.⁵ However, the times to peak concentration, onset, and duration of EEG activities were remarkably different among the three drugs (Table A23–2).

TABLE A23–2. Selected Pharmacokinetic and Pharmacodynamic Properties of Benzodiazepines in Animals⁵

Parameter	Diazepam	Midazolam	Lorazepam
Time to peak CSF concentration (minutes)	3.7 ± 1.3	3.7 ± 1.3	7.0 ± 4.2
Onset of EEG activity (minutes)	0.89 ± 0.31	0.29 ± 0.04	3.8 ± 3.1
Duration of EEG activity (minutes)	7.5 ± 1.4	6.3 ± 1.9	28.3 ± 10.1

CSF = cerebrospinal fluid; EEG = electroencephalographic.

In a similar study, human volunteers were given a one minute intravenous infusion of either diazepam (0.15 mg/kg) or midazolam (0.1 mg/kg) and EEG analysis was used as a surrogate for the pharmacodynamic effects of sedation. Peak EEG

effects were present immediately at the end of the diazepam infusion, but were delayed for 5 to 10 minutes after the midazolam infusion.³² These EEG effects lasted for 5 hours in diazepam-treated volunteers in comparison to only 2 hours in midazolam-treated volunteers. The same investigators compared the EEG effects of either intravenous lorazepam (low dose, 0.0225 mg/kg; high dose, 0.045 mg/kg) or diazepam (0.15 mg/kg) in human volunteers.³¹ In comparison to diazepam, the EEG effects of lorazepam were slower in onset, delayed in peak (30 minutes), and prolonged in duration of effect. This may be related in part to a relatively long alpha distribution half-life for lorazepam.³⁰ When another group compared the EEG effects of intranasal to intravenous midazolam they demonstrated the onset of EEG effects within 1.2 minutes of a 5 mg intravenous dose.³⁵ The relative effects of diazepam, lorazepam, and midazolam are shown in [Table A23–3](#).

TABLE A23–3. Relative Pharmacodynamic Properties of Benzodiazepines in Humans

	<i>Diazepam</i>	<i>Midazolam</i>	<i>Lorazepam</i>
Anticonvulsant			
Onset of action			
IV	Rapid (minutes)	Rapid (minutes)	Rapid (minutes)
IM	Not advisable	~3 minutes	9 minutes
Duration of action			
IV	1–2 hours	30–80 minutes	Many hours
IM	Unpredictable	1–2 hours	Many hours
Sedative			
Onset of action			
IV	Rapid (minutes)	Rapid (minutes)	5–20 minutes
IM	Unpredictable	5–10 minutes	20–30 minutes
Relative duration of action			
Single dose	Short	Short	Long
Repeated doses	Long (secondary to active metabolites)	Intermediate (secondary to active metabolites)	Long

IV = intravenous; IM = intramuscular.

ROLE OF BENZODIAZEPINES IN SELECT POISONINGS: THEORETICAL ASPECTS SUPPORTING A TRYPTOPHAN-RICH SENSORY PROTEIN INTERACTION

Many chapters in this text discuss the use of benzodiazepines as GABA_A agonists in the management of poisoned patients ([Chaps. 14, 15, 75, 76, 78, 81, 82, and 86](#)). In contrast to the highly evidence-based support for GABA_A agonists in sympathomimetic overdose, xenobiotic-induced seizures, and sedative-hypnotic withdrawal, the use of benzodiazepines as modulators of TSPOs for the treatment of poisoned patients is highly speculative. However, as this field is rapidly evolving, discussions of two xenobiotics, chloroquine ([Chap. 59](#)) and cocaine ([Chap. 78](#)) are warranted.

Chloroquine

Although chloroquine overdose is uncommon, case fatality rates are extremely high, and ingestion of 5 g or more was once considered universally fatal. However, in 1988 a case series of patients with chloroquine overdose who survived with the use of an aggressive new regimen was described.⁷² The protocol, consisting of early endotracheal intubation, high-dose epinephrine infusion, and intravenous diazepam (2 mg/kg over 30 minutes), resulted in the survival of 10 of 11 patients who ingested at least 5 g of chloroquine. This regimen was based on a controlled trial where diazepam improved the hemodynamic and electrocardiographic manifestations of chloroquine poisoning in pigs.⁷³ Although the study was not designed to determine the mechanism of effect of diazepam, there was no difference in the chloroquine concentrations between the treated and control groups, suggesting that diazepam did not change the distribution of chloroquine.

In isolated perfused hearts, high-dose diazepam has positive inotropic effects that are suppressed by a TSPO antagonist.⁵⁰ Unfortunately, translation of these findings to use in human poisoning is not necessarily valid. Benzodiazepines, chloroquine, and experimental TSPO agonists share some structural elements, suggesting a receptor-

based mechanism (Fig. A23–4). Functional similarity is also suggested by evidence that both flurazepam and PK 11195 (a TSPO agonist) have antimalarial activity.²² Thus, one could speculate that it is possible that the beneficial effects of high-dose diazepam result from competitive inhibition between chloroquine and TSPOs.

FIGURE A23–4. Comparative structures of flurazepam, PK 11195 (a PBR agonist), and chloroquine. Note the similarity and particularly the shared isoquinoline rings of chloroquine and PK 11195.

Cocaine

Patients who use cocaine frequently present to emergency departments with chest pain or signs or symptoms that could represent myocardial ischemia or infarction.¹² Unlike most patients with acute cocaine toxicity, however, these patients often present hours after their last drug use and without the classic sympathomimetic findings of acute cocaine toxicity.³⁶ While the pathophysiology of cocaine-induced myocardial ischemia is complex and multifactorial (Chap. 76), one component of delayed myocardial ischemia may result from the vasoconstrictive actions of benzoylecgonine, the principal metabolite of cocaine.⁵⁴ Benzoylecgonine is distinct from cocaine in that it has a much longer half-life,^{3,4} does not produce central nervous system stimulation,^{61,62} and directly vasoconstricts through modulation of calcium channels.⁵³

Limited research suggests that chronic cocaine use is associated with an increased number of TSPOs on human platelets.¹⁶ Also in humans, cocaine withdrawal is associated with a decrease in TSPOs on neutrophils. In the myocardium, TSPOs are either present on mitochondria or coupled to calcium channels.⁶⁰ Specifically, TSPO ligands have inhibitory effects on myocardial L-type calcium channels.¹⁴ Also in experimental models of cardiac ischemia and reperfusion injury, TSPO agonists limit myocardial infarction size and improve cardiac function.^{48,91} This effect most likely occurs through inhibition of the opening of the mitochondrial permeability transition pore,⁶⁵ the opening of which is a common final mechanism of cell death. Additionally, although the exact mechanism is unclear, TSPO agonists directly antagonize the vasoconstrictive effects of norepinephrine in rat aortic tissue.²⁹

Benzodiazepines are commonly used to treat the agitation associated with sympathomimetic overdose (Chaps. 76 and 78). While it is assumed that the normalization of vital signs results from a decrease in central nervous system stimulation and psychomotor agitation, effects on TSPOs may be contributory. In the same isolated perfused hearts described above, low-dose diazepam has a negative inotropic effect that results from an interaction with calcium currents.⁴⁹ As noted above, interpreting the implications of varied benzodiazepine doses in an isolated rat model with regard to human beings may not be valid. More importantly, two randomized controlled studies evaluated the use of benzodiazepines in patients with cocaine-associated chest pain.^{9,37} In the first study, patients were randomized to receive nitroglycerin, diazepam, or combined therapy.⁹ Both drugs were associated with an improvement in chest pain, and combined therapy appeared to offer no additional benefit. The second study randomized patients to nitroglycerin or combined nitroglycerin with lorazepam

therapy.³⁷ In this trial, combined therapy was better than either therapy alone, possibly suggesting that benzodiazepines and nitroglycerin relieve chest pain by different mechanisms.

ADVERSE EFFECTS AND SAFETY ISSUES

The most common adverse effect of benzodiazepines is central nervous system depression. While this is unavoidable in some cases, it can generally be limited by selecting the optimal drug and the proper dose and dosing interval for the drug being used. Extra caution is advised in elderly patients as they appear to be more sensitive, particularly to the sedative and respiratory depressant effects of midazolam.¹ In contrast, paradoxical reactions may occur where patients become more agitated following benzodiazepine administration.^{76,79,87} These infrequent reactions probably result from disinhibition and may respond to larger doses of benzodiazepines. Although paradoxical agitation also responds to flumazenil (Antidotes in Depth: A22), reversal would generally be inappropriate following the use of benzodiazepines for most toxicological indications.

Intravenous benzodiazepines produce a mild reduction in heart rate and both systolic and diastolic blood pressure. The effects of midazolam may be greater than diazepam,⁷⁰ but this may merely be based on an inability to determine an equivalent dosing regimen. While these reductions result in part from diminished sympathetic tone, direct myocardial effects are rarely severe and are often considered desirable in the overdose setting.⁷⁰

Whereas respiratory depression is generally not a concern with oral benzodiazepines, parenteral administration is documented to impair ventilation. Early investigations demonstrated that intramuscular diazepam (10 mg) blunted the hypoxic ventilatory drive in normal subjects.⁴⁶ Intravenous diazepam impaired the ventilatory response to a rising PCO₂ in normal volunteers.⁸ The impaired response to a rising PCO₂ was evident almost immediately and lasted for at least 25 minutes following injection of 0.4 mg/kg of diazepam in healthy volunteers.³⁴ Studies with midazolam demonstrate similar alterations in respiratory physiology²⁵ that are comparable in magnitude to those reported with diazepam.¹⁰ Apnea is reported following intravenous midazolam and appears to be dose and rate related, with doses greater than or equal to 0.15 mg/kg being of particular concern.⁴⁸ Individuals with preexisting pulmonary disorders, extremes of age, or other central nervous system or respiratory depressants may be more susceptible. When intramuscular midazolam is used for the treatment of agitation, some transient respiratory depression is noted, but the need for external ventilator support is uncommon.^{40,43,56}

Pregnancy and Lactation

Diazepam, lorazepam, and midazolam are all listed as category D drugs in pregnancy and are likely unsafe in lactation. These classifications are likely based on repetitive use and have little applicability to short-term benzodiazepine administration in emergent situations. However, the risks, benefits, and alternatives should always be considered prior to giving any xenobiotic to a pregnant woman. If a benzodiazepine is given to a lactating mother, “pumping and dumping” would be advised to prevent sedation in the child (Chap. 31).

DOSING AND ADMINISTRATION

In theory, an analysis of the pharmacokinetic and pharmacodynamic parameters presented in Tables A23–1 and A23–3 should allow clinicians to choose among the benzodiazepines based on the particular clinical situation. In reality, however, these choices may be difficult in patients with complex clinical presentations of uncertain etiologies. In addition, clinical studies seem to suggest less variability than might be predicted based on pharmacokinetic and pharmacodynamic modeling. For example, in an analysis of 28 studies of conscious sedation, 19 failed to demonstrate a significant difference in the times to recovery between diazepam and midazolam.⁶ Likewise, although multiple studies demonstrate that lorazepam is at least as effective and likely superior to diazepam in terminating status epilepticus, its onset of action does not appear to be delayed.^{2,51,82} In a double-blind trial of intravenous lorazepam versus intramuscular midazolam for patients with prehospital status epilepticus, patients who received intramuscular midazolam stopped seizing sooner and in greater numbers.⁷⁸

Some of the observed inability to translate controlled pharmacologic analyses into clinical practice may result from imprecision in determining equivalent doses of these drugs. We offer the following guidance. Each of these three benzodiazepines discussed will likely have some efficacy in all clinical scenarios for which a benzodiazepine is indicated. It may therefore be preferable for many clinicians to understand and master the pharmacology and limitations of a single drug rather than attempt to use all three drugs selectively and run the risk of an improper dose or suboptimal therapeutic interval leading to an adverse effect. For those who wish to use these drugs selectively, three variables should be considered: onset of effect, peak effect, and duration of effect. For example, in patients with extreme psychomotor agitation intravenous diazepam or midazolam would be preferred both for their rapid onset and rapid peak effects. The relatively

slow onset and delayed peak of lorazepam might lead to administration of multiple doses before the full effect of the first dose is appreciated, with resultant oversedation. When a short duration of sedation is anticipated, such as when treating a patient with toxicity following intravenous or inhaled use of cocaine, midazolam might be preferable over diazepam or lorazepam in that the duration of the effects of midazolam better matches the duration of effects of cocaine, thereby limiting oversedation after cocaine has been rapidly metabolized. For disorders where very long periods of agitation are expected, such as alcohol withdrawal, the choice of diazepam with its active metabolites (desmethyldiazepam and oxazepam) may be preferable over lorazepam and midazolam. With diazepam, less frequent dosing may be required and an auto-tapering effect may result at the end of therapy, because these metabolites persist longer than diazepam alone. When status epilepticus is present in the absence of substance use or withdrawal, midazolam in large doses seems to offer a clear advantage. It is important to note that switching from one benzodiazepine to another is rarely indicated and increases the risk of an adverse drug event from unpredictable peak effects or improper therapeutic doses or dosing intervals. Specific recommendations can be found in [Chaps. 15, 76, 78, and 81](#).

FORMULATION AND ACQUISITION

Parenteral benzodiazepines are available from multiple manufacturers in varying concentrations. It is essential to recognize that some formulations contain several significant and varied excipients ([Table A23–1](#)). Large doses or prolonged continuous infusions of benzodiazepines may result in toxicity from these excipients ([Chap. 55](#)).

SUMMARY

- Although benzodiazepines are commonly used in a variety of medical settings, subtle differences exist in their pharmacokinetics and pharmacodynamics. Optimal use of these drugs requires a thorough understanding of these differences.
- Clinicians should consider the desired onset of action, peak effect, and duration of action when choosing among different benzodiazepines.
- In general, intravenous administration is preferred in an emergency because of rapid and reliable absorption. Because of a rapid onset of action and short time to peak effect, sedation is best achieved with midazolam when a short duration of action is desirable, or diazepam for a longer duration of action.
- When intravenous access is not available, pharmacokinetic and pharmacodynamic parameters favor the use of midazolam for sedation.
- When used for sedation, the delayed peak effect of lorazepam (regardless of route of administration) is undesirable.
- Intravenous lorazepam is highly effective for seizures, but a continuous infusion of midazolam is preferred for status epilepticus.
- Although the use of benzodiazepines as TSPO (peripheral benzodiazepine receptor) agonists may explain some unique therapeutic effects of these drugs, existing research is too limited to offer guidance with regard to choice of drug, dose, or dosing interval required to optimize peripheral benzodiazepine receptor response.

79 DISULFIRAM AND DISULFIRAMLIKE REACTIONS

Amit K. Gupta

HISTORY AND EPIDEMIOLOGY

Disulfiram tetraethylthiuram disulfide (TETD) was synthesized from thiocarbamide in the 1880s to accelerate the vulcanization (stabilization) of rubber by the addition of sulfur.¹⁰⁴ Sixty years later it was the first western medication used to treat alcohol dependence. By the turn of the 20th century, most rubber factory workers exposed to disulfiram found that they were intolerant to alcohol.^{2,32} Williams, a rubber factory occupational physician, wrote, “If the chemical compound disulfiram is not harmful to man, one wonders if one has discovered a cure for alcoholism.” Apart from its use in the rubber industry, beginning in the early 1940s disulfiram was also used in medicine as a scabicide. Two scientists, Hald and Jacobsen, were exploring the antiparasitic effects of disulfiram when they made the rediscovery that ingesting alcohol after loading doses of disulfiram was quite unpleasant.³⁶ Subsequently, in 1951 the US Food and Drug Administration (FDA) approved disulfiram for the treatment for alcoholism. Disulfiram is typically prescribed at an initial dose of 500 mg/day for 1 to 2 weeks, followed by a maintenance dose of 125 to 500 mg/day.

Disulfiram was never widely used clinically, and its use further declined after the several studies revealed no significant difference in drinking outcomes between unsupervised disulfiram administration and placebo.³¹ Studies evaluating the efficacy of disulfiram span nearly 60 years and yield mixed results, with many studies having small sample sizes, nonrandomization, unblinded conditions, short follow-up periods, and no measurement of treatment adherence. With the worldwide approval of naltrexone in 1993, and later acamprosate, the clinical use of disulfiram declined. More recent interest in disulfiram for treating cocaine and other stimulant dependence has provided some renewed clinical interest.^{33,79,82,99}

Specific epidemiologic information about the three different forms of disulfiram toxicity is difficult to elucidate, even from an analysis of the American Association of Poison Control Centers (AAPCC). Data from the Annual Reports of the AAPCC National Poison Data System from 2007 to 2011 revealed 368 exposures to disulfiram, with the majority of cases being in adults and classified as unintentional. No deaths and only two major adverse outcomes were reported. Since 1982, 14 deaths associated with disulfiram have been reported to the AAPCC, most involving a disulfiram–ethanol reaction (Chap. 136). Serious adverse effects associated with both therapeutic use of disulfiram and with disulfiram overdose continue to be reported mostly in the form of case reports and case series. As such, these reports are difficult to interpret because of complications and comorbidities associated with alcohol use, the potential effects of polypharmacy, and the difficulty in relating the adverse effect to disulfiram, alcohol or a disulfiram–ethanol reaction.

In considering disulfiram toxicity, a distinction must be made between the clinical manifestations of a disulfiram–ethanol reaction and the toxic effects of disulfiram itself. Direct disulfiram toxicity can be further classified as acute or chronic poisoning. Although life-threatening effects associated with disulfiram are rare, clinicians should be aware of proper diagnosis and management of patients with disulfiram-associated toxicity.

PHARMACOLOGY AND PHARMACOKINETICS OF DISULFIRAM

Approximately 70% to 90% of disulfiram is absorbed from the gastrointestinal tract after oral administration.¹² Upon absorption, disulfiram is immediately converted to diethyldithiocarbamate (DDC), followed by rapid conversion to carbon disulfide and diethylamine.²² DDC can also chelate copper to form a bis(DDC)-copper complex.¹² Bis(DDC)-copper is absorbed from the small intestine. In one study, the mean serum disulfiram concentration in humans following a 250 mg

dose was reported to be $0.38 \pm 0.03 \mu\text{g/mL}$.²² Peak serum concentrations of disulfiram and DDC are achieved 8 to 10 hours following a 250 mg dose and 5 to 6 hours for carbon disulfide.²²

Disulfiram is highly lipid soluble and approximately 80% protein-bound.⁴³ An estimated 5% to 20% is not metabolized and is excreted unchanged in the feces. The volume of distribution has not been reported.

Within 5 to 10 minutes after absorption, disulfiram is rapidly reduced to DDC via glutathione reductase, which then can undergo nonenzymatic degradation to diethylamine and carbon disulfide or chelate copper to form a bis(DDC)-copper complex (Fig. 79–1).¹² As such, it may be difficult to detect the parent drug in blood concentrations. Metabolism of disulfiram occurs primarily in the liver and the erythrocyte. The oxidation of DDC in the liver is catalyzed by at least four isoenzymes of cytochrome P450 (CYP) and to a minor extent by human flavin monooxygenase.⁶⁰ DDC is also metabolized by glucuronidation, methylation, and oxidation. Methylation of DDC produces diethyldithiomethylcarbamate (MeDDC).¹⁵ MeDDC is oxidized primarily to the intermediate metabolite MeDDC sulfine, which is ultimately converted to MeDDC sulfoxide.⁶⁰ Genetic differences in various enzymatic activity between individuals can lead to fluctuating concentrations of the different metabolites.²² Carbon disulfide can undergo oxidation to carbonyl sulfide and further oxidation to carbon dioxide.

FIGURE 79–1 Disulfiram metabolism occurs in the liver and in the erythrocyte. The most consequential metabolites are diethyldithiocarbamate and carbon disulfide.

The hepatic metabolites of disulfiram are mostly excreted renally, although up to 20% of disulfiram can pass unchanged in the feces.²² Disulfiram has a half-life estimated at 60 to 120 hours. DDC is estimated to have a half-life of 13.9 hours and carbon disulfide 8.9 hours.⁴² With chronic dosing of disulfiram, carbon disulfide may also be excreted through the lungs, and this may explain the side effects of metallic taste and halitosis.²² Because of the long half-lives of disulfiram and its metabolites, 1 or 2 weeks may be needed before disulfiram is totally eliminated from the body following the last dose.²

DISULFIRAM–ETHANOL REACTION

Pharmacology and Pharmacokinetics

The primary indication for disulfiram is as an avoidant and aversive treatment for alcohol dependence. Either the fear of having a disulfiram–ethanol reaction or the memory of having one is a form of conditioned avoidance meant to deter the patient from using alcohol. Disulfiram inhibits both cytosolic and mitochondrial hepatic aldehyde–nicotinamide adenine dinucleotide (NAD) oxidoreductase, which is more commonly known as aldehyde dehydrogenase (ALDH), the enzyme that catalyzes the oxidation of acetaldehyde to acetate, resulting in an accumulation of acetaldehyde in the blood and tissues after ethanol ingestion (Fig. 79–2).² The increased concentration of acetaldehyde is responsible for the symptoms produced by the disulfiram–ethanol reaction.

FIGURE 79–2 The site of action of disulfiram. The irreversible inactivation of aldehyde dehydrogenase results in an increased acetaldehyde concentration after ethanol is administered.

Elevations of blood acetaldehyde are largely determined by the extent of ALDH inhibition produced as well as the ethanol dose ingested.⁸⁰ After oral disulfiram administration, low-Km ALDH is inhibited with dosages greater than 150 mg/kg, but disulfiram does not inhibit high-Km ALDH even in high dosages (eg, 600 mg/kg).⁶⁴ ALDH will be inhibited by disulfiram at a more-or-less constant rate regardless of variations in the concentration of ALDH. ALDH inhibition with disulfiram develops over 12 hours and is mainly irreversible.⁴³ Recovery of enzymatic activity depends on de novo ALDH synthesis that takes place in 6 or more days.⁵⁰ The exact mechanism by which disulfiram and its metabolites inhibit ALDH is still unknown but may be due to oxidizing sulfhydryl groups or competition for NAD.⁹⁰ The metabolites of disulfiram, including DDC and its sulfoxide and sulfone metabolites, also inhibit ALDH.³⁶

The disulfiram–ethanol reaction may occur up to 3 weeks after the cessation of disulfiram therapy. There are also sustained-release and depot disulfiram preparations, but none are available in the United States. One patient developed a reaction 3 weeks after the subcutaneous injection of 2 g of disulfiram.⁸³

Disulfiram–ethanol reactions may follow exposure to the ethanol contained in many household products containing ethanol. [Table 79–1](#) lists some of these products.

TABLE 79–1. Common Household Products That Contain Ethanol and May Cause a Reaction with Disulfiram^{20,55,81,83,90}

Adhesives
Alcohols: denatured alcohol, rubbing alcohol
Detergents
Foods: liquor containing desserts, fermented vinegar, some sauces
Nonprescription xenobiotics: analgesics, antacids, antidiarrheals, cough and cold preparations, topical anesthetics, vitamins
Personal hygiene products: after shave lotions, colognes, contact lens solutions, deodorants, liquid soaps, mouthwashes, perfumes, shampoos, skin liniments, and lotions
Solvents

Clinical Manifestations

Symptoms of the disulfiram–ethanol reaction often begin within 15 minutes of ethanol ingestion, peak at 30 to 60 minutes, and gradually resolve over the next several hours. Symptoms are diverse and can include flushing, pruritus, diaphoresis, lightheadedness, headache, nausea, vomiting, and abdominal pain. Esophageal rupture due to forceful vomiting has been reported.²⁴ Electrocardiogram (ECG) changes, including ST-segment depressions and flattening of T waves, can occur along with dysrhythmias and myocardial infarction.^{67,71} Other rare complications include methemoglobinemia, hypertension, bronchospasm, and myoclonus.^{102,105,117} Severe shock and hypotension requiring vasopressor support is reported.^{10,70} Deaths attributed to the disulfiram–ethanol reaction are extremely rare and are associated with disulfiram doses in excess of current recommendations.^{4,44}

Disulfiramlike reactions can occur when ethanol is ingested with xenobiotics other than disulfiram. Symptoms are similar to those of disulfiram–ethanol reactions. Health care providers should warn patients of such reactions when prescribing certain medications that may cause this adverse effect. Unfortunately, these reactions are idiosyncratic and have not been studied extensively.¹¹¹ [Table 79–2](#) lists xenobiotics reported to cause disulfiramlike reactions.

TABLE 79–2. Xenobiotics Reported to Cause a Disulfiramlike Reaction with Ethanol^{7,1313,21,38,52,53,69,73,95,109,113,116}

Antimicrobials

Cephalosporins, especially those that contain an n-methylthiotetrazole (nMTT) side chain, such as cefotetan, cefoperazone, cefamandole, and cefmenoxime

Metronidazole

Moxalactam

Trimethoprim-sulfamethoxazole

Possible reactions with chloramphenicol, furazolidone, griseofulvin, nitrofurantoin, procarbazine quinacrine, sulfonamides

Calcium carbimide (citrated)

Carbon disulfide

Carbon tetrachloride

Chloral hydrate

Dimethylformamide

Mushrooms

Coprinus mushrooms including *C. atramentarius*, *C. insignis*, *C. variegatus*, and *C. quadrifidus*, *Boletus luridus*, *Clitocybe clavipes*, *Polyporus sulphureus*, *Pholiota squarosa*, *Tricholoma aurantium*, *Verpa bohemica*

Nitrefazole

Phentolamine

Sulfonylurea oral hypoglycemics

Chlorpropamide

Tolbutamide

Tacrolimus

Thiram analogs (fungicides)

Copper, mercuric, and sodium diethyldithiocarbamate

Zinc and ferric dimethyldithiocarbamate

Zinc and disodium ethylenebis [dithiocarbamate]

Thiuram analogs

Tetraethylthiuram monosulfide and disulfide (disulfiram)

Tetramethylthiuram disulfide (thiram)

Tolazoline

Trichloroethylene

Ingestion of ethanol following ingestion of various *Coprinus* species of mushrooms can cause a disulfiramlike reaction ([Chap. 120](#)).⁹²

MANAGEMENT OF DISULFIRAM-ETHANOL REACTIONS

The duration of the disulfiram-ethanol reaction varies from 30 to 60 minutes in mild cases to several hours and is largely dependent on the amount of alcohol that needs to be metabolized. Due to vomiting and volume depletion, serum glucose, electrolytes, and kidney function should be evaluated. Since only small amounts of ethanol can precipitate a disulfiram-ethanol reaction, it may be useful to confirm the presence of ethanol with a blood concentration. Patients with cardiovascular instability should have an ECG. Symptomatic and supportive care is the mainstay of treatment. Most patients with hypotension respond to intravenous 0.9% sodium chloride. Refractory hypotension is rare, but if necessary, a vasopressor can be administered. A direct-acting adrenergic agonist such as norepinephrine should be used since disulfiram inhibits dopamine β -hydroxylase (DBH), an enzyme necessary for norepinephrine synthesis. As such, indirect vasopressors, such as dopamine, that require functioning norepinephrine synthesis may be less effective.

For further symptomatic care, antiemetics can be administered, and for cutaneous flushing, a histamine (H_1) receptor antagonist, such as diphenhydramine, can be given.¹⁰¹ Most patients with a disulfiram-ethanol reaction have mild symptoms, are hemodynamically stable, and can be safely discharged following resolution of symptoms.

Fomepizole may halt the accumulation of acetaldehyde and thus cease severe disulfiram-ethanol reactions. Fomepizole, an inhibitor of alcohol dehydrogenase, may terminate the progression of the disulfiram reaction by blocking ethanol metabolism to acetaldehyde (Antidotes in Depth: A30). In a study of alcoholics, fomepizole decreased acetaldehyde concentrations and improved clinical symptoms in those experiencing a disulfiram-ethanol reaction.⁵⁹ A recent case series reported two patients who developed severe disulfiram-ethanol reactions with hypotension and tachycardia unresponsive to fluids who were treated successfully with a single dose of fomepizole.⁹⁷ One patient improved clinically 90 minutes after administration of fomepizole and the other within 30 minutes.

OTHER ENZYMES INHIBITED BY DISULFIRAM

Disulfiram and its active metabolites have many other targets besides ALDH. DDC is a potent metal chelator, which explains interest in the treatment of nickel and its effects on the activity of copper-dependent enzymes such as microsomal carboxylesterases, plasma cholinesterases, and cytochrome oxidase.⁶³ Inhibition of microsomal carboxylesterases and plasma cholinesterases are theorized to play a role in the pharmacokinetic increases in plasma cocaine concentrations caused by disulfiram.⁶⁵ Drugs metabolized by the cytochrome oxidase systems CYP450, specifically CYP2E1 (such as amitriptyline, warfarin, phenytoin, chlorthalidone, and diazepam) have increased serum concentrations and prolonged half-lives in patients taking disulfiram.³⁰

DDC also inhibits DBH, which converts dopamine to norepinephrine.^{34,72} Inhibition of DBH leads to increased concentrations of dopamine in the brain and periphery and decreased concentrations of norepinephrine and epinephrine.³⁴ The increased concentrations of dopamine from disulfiram may explain its possible therapeutic benefit in cocaine dependence and the potentiation of psychosis in psychotic individuals. Decreased urinary concentrations of vanillylmandelic acid, the metabolite of epinephrine and norepinephrine, are noted in individuals taking disulfiram, and this may explain the hypotension that occurs in patients with the disulfiram-ethanol reaction.³⁷

DISULFIRAM AND THE CYTOCHROME P450 OXIDATION SYSTEM

Disulfiram and its primary metabolite DDC are selective mechanism-based inhibitors of CYP2E1.⁴⁸ One study demonstrated in normal healthy volunteers that a single 500 mg dose of disulfiram markedly reduced by 93% the six-hydroxylation of chlorzoxazone, a putative index of CYP2E1 activity.⁴⁹ These same investigators showed, using probe drugs selectively metabolized by individual CYP enzymes, that 500 mg of disulfiram had no effect on the metabolism of coumarin (CYP2A6), tolbutamide (CYP2C9), mephenytoin (CYP2C19), dextromethorphan (CYP2D6), or intravenously administered midazolam (CYP3A).⁴⁸ Disulfiram does not significantly alter the metabolism of a therapeutic dose of acetaminophen, in either healthy patients or those with alcoholic liver disease.⁸⁴

DISULFIRAM AS AN ANTIDOTE

Disulfiram has been used for the treatment of nickel dermatitis. However, a small double-blind, placebo-controlled study of patients with hand eczema and nickel allergy did not find a clinically significant difference between those treated with disulfiram and those treated with placebo.⁴⁵ In fact, the conditions of some patients worsened after disulfiram therapy.⁵¹

DDC is available as the chelator dithiocarbamate. Although animal data and human case series suggest that DDC may be an effective chelator for the treatment of nickel-carbonyl poisoning, no well controlled human studies exist. Although animal studies suggest that DDC may be effective for nickel-carbonyl poisoning, there are no human studies to confirm this.^{11,103}

Since disulfiram increases nickel absorption in humans, it is recommended to consider use of disulfiram or DDC only for the treatment of nickel-carbonyl poisoning and not for elemental or inorganic nickel poisoning.

OTHER CLINICAL MANIFESTATIONS

Acute Disulfiram Toxicity

Reported cases of acute disulfiram overdose are rare and typically do not cause life-threatening toxicity. Most patients rapidly develop gastrointestinal symptoms within 1 to 2 hours that include nausea, vomiting, and abdominal pain. Neurologic symptoms may also be present after acute disulfiram overdose, including lethargy and coma.⁵⁸ Dysarthria and movement disorders, including myoclonus, ataxia, dystonia, and akinesia, occur rarely and may be related to direct effects of carbon disulfide on the basal ganglia.^{56,57,61} Symptoms can start as early as 3 days after ingestion. Hypotonia may be present in children.⁵ Persistent neurologic abnormalities, such as paresis, myoclonus, and neuropathy, lasting weeks to months, are reported in both children and adults but are rare.^{91,118}

Chronic Disulfiram Toxicity

The disulfiram-ethanol reaction, characterized by tachycardia, hypotension, diaphoresis, and facial erythema, is familiar to most physicians. However, the toxic effects of disulfiram alone, including depression, lethargy, loss of libido, psychosis, delirium, meningeal signs, unilateral weakness, optic neuritis, and peripheral neuropathy, are not well recognized by most clinicians, perhaps because the behavioral symptoms can be confused with manic-depressive or schizophrenic psychoses and the neurologic findings with the sequelae of alcoholism.^{17,21,25,54,77,89,96}

Two placebo-controlled trials showed no greater incidence of adverse effects with disulfiram 250 mg daily versus placebo other than drowsiness in the absence of alcohol.³¹ Over a 23 year period (1968–1991), 155 adverse drug reactions (ADR) were reported for disulfiram, giving it an ADR rate of 1 per 200 to 2000 patients per year (categorized as an “intermediate” rate of ADRs for a medication). Hepatic reactions were the most frequent ADR (34%), followed by neurologic (21%), cutaneous (15%), psychiatric (4%), and other (26%).²¹

Disulfiram-induced hepatitis was first reported in 1974.⁴⁷ In 1977, six additional cases were reported; five of the patients died.⁸⁸ Incidence of disulfiram-induced fatal hepatitis is reportedly 1 in 30,000 patients treated per year.¹⁴ The onset of symptoms of hepatotoxicity due to disulfiram occurs within 4 to 6 weeks (range, 2–24 weeks) after initiating treatment.^{14,27,88} Signs and symptoms include fatigue, headache, fever, pruritus, rash, myalgia, malaise, anorexia, nausea, vomiting, abdominal pain, jaundice, light stools, dark urine, and hepatomegaly. Symptoms usually resolve within 2 weeks of stopping disulfiram, but liver function may require up to 12 weeks to normalize.^{14,27,88} Liver biopsy may show predominantly hepatocellular degeneration with focal or extensive hepatocellular necrosis as well as portal and periportal eosinophilic infiltration.^{14,27} Although the exact mechanism of disulfiram-induced liver damage is unclear, most reports suggest an idiosyncratic hypersensitivity reaction as the primary mechanism involved.^{14,27,88} Alternatively, a carbon disulfide-induced hepatic injury resulting from covalent binding of electrophilic oxides or carbene derivatives of these oxides to macromolecules may be responsible.²⁸

Asymptomatic elevations in aminotransferase concentrations, up to three times the upper limit of normal, associated with disulfiram therapy are reported to range from 6% to 30% in alcoholics.^{35,106,115} Although hepatic effects have most commonly been reported with oral dosage forms, they also occur with implantable disulfiram.⁶⁶

Liver transplantation for disulfiram-induced liver failure was first reported in 1989.¹¹⁰ Since then, several case reports of liver transplantation for disulfiram-induced liver failure have been noted⁶⁸; the first North American case was performed in 1988.⁸⁶

Disulfiram may induce a peripheral neuropathy characterized by distal sensory impairment with loss of coordination, painful paresthesias, and distal weakness with foot drop.^{1,29} The severity of the neuropathy is directly related to dose and duration of exposure.^{78,112} If disulfiram is not discontinued, sensory and motor impairment can progress proximally.^{6,93} Wallerian-type axonal degeneration, intermediate filament accumulation, and marked loss of larger myelinated fibers have long been considered the pathological hallmarks of disulfiram toxicity.^{9,76} Experiments in animals showed that disulfiram causes Schwann cell damage and demyelination of peripheral nerves.^{107,108} In addition, isolated descriptions of both axonal and myelin involvement are reported.⁷⁵

The mechanisms underlying disulfiram-induced parkinsonism or catatonia are still controversial. One of the main hypotheses is that the lesions result from the toxicity of the disulfiram metabolite, carbon disulfide.^{46,87} Histopathological lesions of the globus pallidus and substantia nigra are observed after chronic exposure to carbon disulfide in animals.⁹³ Others have suggested involvement of brain dopaminergic transmission in disulfiram neurotoxicity.^{16,41} This is supported by an experiment in mice, where the toxic effects of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine on nigrostriatal

dopaminergic systems were enhanced by pretreatment with disulfiram.¹⁶

The exact mechanism of disulfiram-mediated encephalopathy is not known. However, both DDC and carbon disulfide have been implicated, and both inhibit the activity of DBH, leading to the accumulation of dopamine, producing a relative deficiency of adrenaline and noradrenaline in the area of the basal ganglia.³⁹ Dopamine-mediated cellular injury may be related to its ability to induce excitatory toxic effects of glutamate and calcium-mediated cell death, as well as to impair the cellular ability to eliminate free oxygen radicals.⁹⁴

Disulfiram and Carbon Disulfide

Carbon disulfide is a colorless volatile liquid and a commonly used nonpolar chemical solvent. The principal industrial use of carbon disulfide is the manufacture of viscose rayon. In addition, carbon disulfide is used as an insecticide for the fumigation of grains, nursery stock, in fresh fruit conservation, and as a soil pesticide against insects and nematodes.¹⁹ The clinical, biochemical, and pathologic neurotoxic effects of disulfiram are similar to those of carbon disulfide. Both are associated with depression, lethargy, loss of libido, psychosis, ataxia, incoordination, and peripheral neuropathy.⁸⁷ Both inhibit DBH in vitro and produce increased brain dopamine and decreased brain norepinephrine, demyelination, and denervation in vivo.¹⁰⁰ Acute exposure to carbon disulfide causes rapid onset of headache, confusion, nausea, hallucinations, delirium, seizures, coma, and potentially death.³ Carbon disulfide may cause seizures by interacting with pyridoxal-5-phosphate, a cofactor in the production of γ -aminobutyric acid (GABA) from glutamate, thereby depleting GABA concentrations in the brain and leading to benzodiazepine-resistant seizures.⁸⁵

Although patients with occupational exposure to carbon disulfide have an increased risk of atherosclerosis and ischemic heart disease, this has not been proven for patients utilizing disulfiram.¹⁰⁴ Disulfiram therapy may increase serum cholesterol concentration.⁶²

Disulfiram and Pediatrics

The presence of this drug in the household makes it a potential xenobiotic encountered in unintentional poisonings; however, reports of significant toxicity are rare. One case report details a 5 year-old girl with exposure to 19 tablets of disulfiram, who subsequently developed dystonia, complete loss of developmental milestones, and spastic tetraparesis, over a 2-year follow-up period.⁶¹

Disulfiram and Pregnancy

There is a paucity of information regarding the teratogenic effects, if any, of disulfiram in humans or animals. Case reports have reported congenital defects, and one spontaneous miscarriage occurred.^{23,40,74} A confounder could be the combination of disulfiram and alcohol itself, which enhances the incidence of birth defects. The embryotoxic properties of disulfiram may also be due to its lead- and copper-chelating properties.¹⁸

DIAGNOSTIC TESTING

Acute Disulfiram Toxicity

Serum disulfiram concentrations are not useful when managing most patients with suspected acute or chronic disulfiram overdose, disulfiram toxicity, or a disulfiram-ethanol reaction. Because of rapid metabolism, only a small proportion of ingested disulfiram reaches the blood as the parent drug.⁴³ Metabolites of disulfiram, including diethyldithiomethylcarbamic acid and diethylmethylcarbamic acid, can be measured in the serum. Other markers of ingestion include carbon disulfide in the breath and diethylamine in the urine.²⁶ Leukocyte ALDH correlates most closely with hepatic mitochondrial ALDH. Decreased erythrocyte ALDH1 and leukocyte ALDH2 activity are markers of disulfiram exposure, but neither enzyme assay is commonly available. Elevated acetaldehyde concentrations in the blood will occur but are not readily available and therefore are not clinically useful in managing the majority of patients.

Chronic Disulfiram Toxicity

The development of hepatotoxicity is a potential concern with chronic disulfiram administration. Two common strategies employed for detecting and preventing severe hepatotoxicity include routine clinical monitoring for signs or symptoms of hepatic injury as well as periodic monitoring of biomarkers including alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, and total bilirubin.^{114,115}

There is no agreement on when disulfiram therapy should be modified or discontinued based on the finding of mildly elevated aminotransferase concentrations. There is much greater agreement that the development of an aminotransferase concentration greater than 3 times the upper limit of the reference range in combination with evidence of impaired hepatic

synthetic function, elevated total bilirubin greater than 2 times the upper limit of the reference range or international normalized ratio greater than 1.5 is suggestive of more severe drug-induced liver injury. In such situations, mortality may be 16% or higher and necessitate discontinuing disulfiram.^{8,98}

MANAGEMENT OF DISULFIRAM TOXICITY

Acute Disulfiram Toxicity

There is no antidote for acute disulfiram overdose. No specific studies have evaluated gastrointestinal decontamination for acute overdose. Unless otherwise contraindicated, activated charcoal at a dose of 1 g/kg can be administered. Forced emesis is not indicated, and orogastric lavage or whole-bowel irrigation is not required.

Chronic Disulfiram Toxicity

Most patients receiving disulfiram will not develop hepatotoxicity, but those who develop mild increase in their aminotransferases will likely normalize with continued disulfiram therapy.⁹⁸ Continued period monitoring of liver function tests should be performed, and therapy should be discontinued with symptoms of hepatic injury such as jaundice, abdominal pain, nausea, vomiting, or fever.

Treatment of hepatotoxicity is supportive and usually resolves following discontinuation of disulfiram therapy. Liver transplantation has been successfully performed for disulfiram-induced hepatic failure in both adults and children.^{68,86}

SUMMARY

- Even though the role of disulfiram in treating alcoholism is diminishing, its use for the treatment of cocaine dependence is gaining interest. It is critical to understand the distinction among the different forms of disulfiram toxicity, including toxicity from an acute overdose, from chronic therapy, and from a disulfiram–ethanol reaction.
- Disulfiram and its metabolites both irreversibly inhibit ALDH. This leads to accumulation of acetaldehyde and is responsible for many of the symptoms produced by the disulfiram–ethanol reaction. Symptoms are typically self-limiting and include facial and generalized body warmth and flushing, pruritus, urticaria, diaphoresis, lightheadedness, vertigo, headache, nausea, vomiting, and abdominal pain.
- Treatment for the disulfiram–ethanol reaction is mostly supportive and includes intravenous crystalloid administration, antiemetics, and histamine receptor antagonists. Fomepizole, an alcoholic dehydrogenase inhibitor, should be considered for more serious reactions.
- Disulfiram toxicity following an acute overdose is unlikely to be life threatening. Early symptoms are mostly gastrointestinal. Rarely, prolonged neurologic symptoms occur and include myopathy, movement disorders, ataxia, parkinsonism, and psychosis.
- Hepatotoxicity is the most common adverse drug reaction associated with chronic disulfiram therapy. Neurotoxicity is also reported with chronic disulfiram toxicity, and, symptoms are similar to those of acute disulfiram toxicity.

80 ETHANOL

Luke Yip

HISTORY AND EPIDEMIOLOGY

Ethanol, or ethyl alcohol, is commonly referred to as “alcohol.” This term is somewhat misleading, because there are numerous other alcohols. However, ethanol is probably the most commonly used and abused xenobiotic in the world. Its use is pervasive among adolescents and adults of all ages, socioeconomic groups, and represents a tremendous financial and social cost.^{3,197} The ethanol content of alcoholic beverages is expressed by volume percent or by proof. Proof is a measure of the absolute ethanol content of distilled liquor, made by determining its specific gravity at an index temperature. In the United Kingdom, the Customs and Excise Act of 1952 declared proof spirits (100 proof) as those in which the weight of the spirits is 12/13 the weight of an equal volume of distilled water at 51°F (11°C). Thus, 100 proof spirits are 48.24% ethanol by weight or 57.06% by volume. Other spirits are designated over or under proof, with the percentage of variance noted. In the United States, a proof spirit (100 proof) is one containing 50% ethanol by volume.

The derivation of proof comes from the days when sailors in the British Navy suspected that the officers were diluting their rum (grog) ration and demanded “proof” that this was not the case. They achieved this by pouring a sample of grog on black granular gunpowder. If the gunpowder ignited by match or spark, the rum was up to standard, 100% proof that the liquor was at least 50% ethanol. This became shortened to 100 proof (Table 80–1).

TABLE 80–1. Basic Information and Calculations

Ethanol molecular weight (MW): 46 Da

$$\text{mmol} = \frac{\text{mg}}{\text{MW}} = \frac{\text{mg}}{46}$$

$$\text{mmol/L} = \frac{\text{mg/dL}}{4.6}$$

Specific gravity: 0.7939 (~0.8) g/mL

Volume of distribution (Vd): 0.6 L/kg

$$\text{Serum ethanol concentration (mg/dL)} = \frac{\text{dose (mg)}}{\text{Vd (L/kg)} \times \text{body weight (kg)} \times 10}$$

Average reduction in blood ethanol concentration (elimination phase):

Nontolerant adult: 3.26–4.35 mmol/L/h (15–20 mg/dL/h,
100–125 mg/kg/h)

Tolerant adult: 6.52–8.70 mmol/L/h (30–40 mg/dL/h, 175 mg/kg/h)

For a 70 kg individual:

<i>Dose of Ethanol</i>	<i>Estimated Serum Ethanol Concentration^a</i>
10 mL/kg of 10% (20 proof)	167 mg/dL (36.30 mmol/L)
3 mL/kg of 10% (20 proof)	50 mg/dL (10.87 mmol/L)
1.5 mL/kg of 10% (20 proof)	25 mg/dL (5.43 mmol/L)
150 mL (5 “shots”) of 40% (80 proof)	143 mg/dL (31.09 mmol/L)
30 mL (1 “shot”) of 40% (80 proof)	27 mg/dL (5.87 mmol/L)
A “standard drink,” defined as 1.5 fluid (fl) oz (eg, a single jigger or shot) of 80 proof spirits (“hard liquor”), 1.5 fl oz (eg, a single jigger or shot) of brandy, 2–3 fl oz of cordial, liqueur, or aperitif, 3–4 fl oz of fortified wine (eg, sherry or port), 5 fl oz of table wine, 8–9 fl oz of malt liquor, or 12 fl oz of regular beer ¹⁵⁸	43 mg/dL (9.35 mmol/L)

^aThis is the theoretical maximum concentration, based on instantaneous and complete ethanol absorption and no distribution or metabolism.

Blood concentration consistent with legal intoxication = 10.87–17.39 mmol/L (50–80 mg/dL or 0.05–0.08 g/dL)

The legal breath ethanol concentration to blood ethanol concentration ratio has been set at 1:2100; the amount of ethanol in 1 mL of blood is the same amount in 2100 mL of exhaled air: Measured breath ethanol concentration (mmol/L) x 2100 = (calculated) blood ethanol concentration (mmol/L).

In addition to beverages, ethanol is present in hundreds of medicinal preparations used as a diluent or solvent in concentrations ranging from 0.3% to 75%.^{28,44,52,145,152,196} Mouthwashes may contain up to 75% ethanol (150 proof), and colognes typically contain 40% to 60% ethanol (80 to 120 proof).^{15,96,152,166} These products occasionally cause intoxication, especially when unintentionally ingested by children.^{31,49,84,198}

Veisalgia, “alcohol hangover,” comes from the Norwegian kveis, “uneasiness following debauchery” and the Greek algia, “pain.” The “hangover” syndrome has been attributed to congeners, substances that appear in alcoholic beverages in addition to ethanol and water.^{26,33,34} Congeners contribute to the special characteristics of taste, flavor, aroma, and color of a beverage. The combinations and exact amounts of congeners vary with the type of beverage, ranging from 33 mg/L in vodka, to averages of 500 mg/L in some whiskies and as much as 29,000 mg/L in specially aged whiskies or brandies.^{26,33,34} The conventional listing of congeners includes fusel oil (a mixture containing amyl, butyl, propyl, and methyl alcohol), aldehydes, furfural, esters, low molecular weight organic acids, phenols, and other carbonyl compounds, tannins, solids, and a relatively large number of additional organic and inorganic compounds, usually in trace amounts.^{26,33}

Consumption of illicitly produced ethanol (“moonshine”) has resulted in methanol, lead or arsenic poisoning, and botulism.^{19,46,66,93,110,116,132,149} Incidental lead contamination is also reported in draught beers or wine contained in lead-capped bottles.^{173,174} Of historic interest is that the addition of cobalt salts to beer to stabilize the “head” (foam) led to

outbreaks of congestive cardiomyopathy among heavy beer drinkers in Canada and Belgium in the 1960s (Chap. 94). The clinical-pathological pattern of this disease is distinct from the classical alcoholic cardiomyopathy.^{126,128}

Alcoholism is the leading cause of morbidity and mortality in the United States. The prevalence of ethanol dependence in the United States has been relatively stable, at around 6% for men and 2% for women.²⁵ The overall estimated annual cost of US health expenses related to ethanol is \$185 billion.¹³⁸ More than 70% of the estimated costs were attributed to lost productivity, most of which resulted from ethanol-related illness or premature death. Most of the remaining estimated costs were expenditures for health care services to treat ethanol induced disorders (14.3%), property and administrative costs of ethanol-related motor vehicle crashes (8.5%), and criminal justice system costs of ethanol-related crime (3.4%). More than 200,000 Americans die annually of alcoholism, far more than those who die of all illicit drugs of abuse combined. Ethanol is the leading cause of mortality in people 15 to 45 years of age. In 2011, there were 9878 ethanol-related traffic fatalities in the United States, which accounted for 31% of total traffic fatalities; 66% of ethanol-impaired driving fatalities involved drivers with blood ethanol concentration 80 mg/dL or higher, 27% were passengers riding with the ethanol-impaired drivers, and 7% were nonoccupants of a motor vehicle.¹³⁷ Drivers aged 21 to 34 accounted for 44%, and drivers between 16 to 20 years accounted for 10% of all ethanol-impaired drivers in fatal crashes. Among 16 to 20 year-old male drivers, an increase of 20 mg/dL in blood ethanol concentration was estimated to more than double the relative risk of fatal single-vehicle crash injury compared with sober drivers of the same age and gender.²⁰⁹ When the blood ethanol concentration ranged from 80 to 100 mg/dL (17–22 mmol/L), 100 to 150 mg/dL (22–33 mmol/L), and greater than 150 mg/dL (33 mmol/L), the relative risk of fatal single-vehicle crash injury was 52, 241 and 15,560, respectively.

The Global Burden of Disease Study identified three effects of ethanol: harmful effects in relation to injuries, harmful effects in relation to disease, and the protective effect in relation to ischemic heart disease.¹³⁸ Overall ethanol accounted for 3.5% of mortality and disability, 1.5% of all deaths, 2.1% of all life years lost, and 6% of all the years lived with disability.¹³⁸ In the United States, according to National Highway Traffic Safety Administration (NHTSA) information, all jurisdictions have enacted per se blood ethanol concentration for adults operating noncommercial motor vehicles.¹³⁷ The term “illegal per se” refers to state laws that make it a criminal offense to operate a motor vehicle at or above a specified ethanol (or drug) concentration in the blood, breath, or urine, which may or may not reflect clinical intoxication (Special Considerations: SC6). For example, although ethanol-tolerant patients may not exhibit impairment even at serum ethanol concentrations greater than 300 mg/dL (65 mmol/L), they are still considered impaired with regard to the laws that governs motor vehicle operation.¹

There is a dose-response relationship between ethanol consumption and risk of death in men aged 16 to 34 and in women aged 16 to 54. Meta-analysis of aggregate data from epidemiologic dose-response ethanol and mortality cohort studies suggests that the level of ethanol consumption at which all-cause risk is lowest is approximately 5 g/d and that ethanol exerts a protective effect (J-shaped dose-response curve) up to a daily intake of approximately 45 g.⁹ It is suggested that sensible drinking of ethanol for men is 8 to 10 g/d up to age 34, 16 to 20 g/d between 34 and 44 years of age, 24 to 30 g/d between 44 and 54 years of age, 32 to 40 g/d up between 54 and 84 years of age, and 40 to 50 g/d over age 85. Women would be advised to limit their drinking to 8 to 10 g/d up to age 44, 16 to 20 g/d between 44 and 74 years of age, and 24 to 30 g/d over age 75.²⁰¹ However, no safe level of prenatal ethanol exposure has been established. The combination of a national tolerance of drinking and heavy advertising of ethanol makes it especially appealing to young people. In a society increasingly concerned with drug abuse, the excessive use of ethanol constitutes a serious and pervasive problem as well as a major health issue.

PHARMACOKINETICS/TOXICOKINETICS

Ethanol is rapidly absorbed from the gastrointestinal (GI) tract, with approximately 20% absorbed from the stomach and the remainder from the small intestine.¹⁴¹ Factors that enhance absorption include rapid gastric emptying, ethanol intake without food, the absence of congeners, dilution of ethanol (maximum absorption occurs at a concentration of 20%), and carbonation. Under optimal conditions for absorption, 80% to 90% of an ingested dose is fully absorbed within 60 minutes. Factors that delay or decrease ethanol absorption include high concentrations of ethanol (by causing pylorospasm), presence of food, coexistence of GI disease, coingestion of xenobiotics such as aspirin and N-butylscopolamine,^{94,146} time taken to ingest the drink, and individual variation. When any of these factors is present, absorption may be delayed for 2 to 6 hours. The relative amount of ethanol that is absorbed from the stomach is determined by the presence of alcohol dehydrogenase (ADH) in the gastric mucosa, which oxidizes a proportion of the ingested ethanol, thus reducing the amount available for absorption. This effect is more pronounced in men than in women and in nonalcoholics than in alcoholics.^{11,58} Histamine₂ (H₂) receptor antagonists such as cimetidine and ranitidine inhibit gastric ADH resulting in decreased first-pass metabolism and increase the bioavailability of imbibed ethanol.^{6,22,24,40,51}

Following complete distribution, ethanol is present in body tissues in a concentration proportional to that of the tissue water content. Ethanol freely passes through the placenta, exposing the fetus to ethanol concentrations comparable to that achieved in the mother.

Ethanol is primarily eliminated by the liver, with 2% to 5% excreted unchanged by the kidneys, lungs, and sweat.⁸⁸ Ethanol is metabolized via at least three different pathways: the aforementioned ADH pathway located in the cytosol of the hepatocytes, CYP2E1, a member of the cytochrome P450 mixed-function oxidase system, located on the endoplasmic reticulum, and the peroxidase-catalase system associated with the hepatic peroxisomes (Fig. 80–1).¹⁴¹

FIGURE 80–1 Ethanol is metabolized to acetaldehyde and then to acetate through major, minor, and inducible pathways. ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase.

For a given ethanol dose, 95% to 98% is metabolized in the liver, first to acetaldehyde by ADH and then further to acetate by aldehyde dehydrogenase (ALDH).⁸⁸ The end products of ethanol oxidation are carbon dioxide and water. The remaining 2% to 5% is excreted unchanged in urine, sweat, and expired air. In addition, less than 0.1% undergoes phase II conjugation reactions to produce ethyl glucuronide and ethyl sulfate, catalyzed by uridine diphosphate-glucuronosyltransferase and sulfotransferase, respectively.^{32,56,76,168,169}

The ADH system is the main pathway for ethanol metabolism and is also the rate-limiting step. ADH is a zinc metalloenzyme that uses oxidized nicotinamide adenine dinucleotide (NAD^+) as a hydrogen ion acceptor to oxidize ethanol to acetaldehyde. In this process, a hydrogen ion is transferred from ethanol to NAD^+ , converting it to its reduced form NADH . Subsequently, a hydrogen ion is transferred from acetaldehyde to NAD^+ . Under normal conditions acetate is converted to acetylcoenzyme A (acetyl-CoA), which enters the Krebs cycle and is metabolized to carbon dioxide and water. The entry of acetyl-CoA into the Krebs cycle is thiamine dependent (Antidotes in Depth: A24).

The ADH gene family encodes enzymes that metabolize a wide variety of substrates. There are at least seven genetic loci that code for human ADH arising from the association of different subunits, and there are more than 20 ADH isoenzymes.² These ADH forms are divided into five major classes (I–V) according to their subunit, isoenzyme composition, and physicochemical properties.⁸⁹ Two of these gene loci exhibit polymorphism and they both involve class I ADH genes; three alleles exist for ADH2 (ADH1B) [ADH2*1 (ADH1B*1), ADH2*2 (ADH1B*2), and ADH2*3 (ADH1B*3)] and three for ADH3 (ADH1C) [ADH3*1 (ADH1C*1), ADH3*2 (ADH1C*2), and ADH3*3 (ADH1C*3)].³⁰ Class I enzymes are inducible intracellular hepatic enzymes and are believed to play a major role in ethanol metabolism.¹¹³ Class IV ADH6 (σ -ADH) is the major ADH expressed in human gastric mucosa.^{11,58} σ -ADH is usually present in non-Asians, whereas in a majority of Pacific Rim Asians, the enzyme activity is either low or not detectable.^{11,12,42} The ADH1B*2 allele is present in 90% of Pacific Rim Asians but occurs infrequently in most Caucasians, except for people of Jewish and perhaps Hispanic descent.²⁰² This allele is responsible for the unusually rapid conversion of ethanol to acetaldehyde. People carrying ADH1B*2 alleles are about one-third as likely to be alcoholic compared with people without this allele.²⁰²

In the liver, ADH metabolizes ethanol to acetaldehyde, which is then converted to acetate by mitochondrial NAD-dependent ALDH. Human ALDH is divided into nine major gene families. There is a functional polymorphism of the mitochondrial ALDH2 gene and expression of an inactive form of the ALDH2, glutamate to lysine substitution at position 487 (E487K), results in impaired acetaldehyde metabolizing capacity. The variant allele ALDH2*2 encodes a protein subunit that confers low activity to the enzyme resulting in marked differences in the steady-state kinetic constants, which appears to be most prevalent in Pacific Rim Asians.^{2,30,68,182,183} These metabolic polymorphisms contribute to differences in ethanol and acetaldehyde elimination rate; high activity ADH variants are predicted to increase the rate of acetaldehyde generation, whereas the low activity ALDH2 variant is associated with limited capacity to metabolize this compound and may explain differences in ethanol-related behavior. Asians possessing an atypical ALDH2 gene are more sensitive to acute adverse responses to ethanol and tend to discourage ethanol consumption. Homozygous ALDH2*2 individuals are strikingly sensitive to small dose of ethanol (0.2 g/kg), as evidenced by the intense flushing, pronounced cardiovascular hemodynamic effects, and subjective perception of general discomfort.^{48,68,150,188,192} This effect may also be associated with the ADH2*2 and ADH3*1 allele and is similar to that induced by disulfiram (Chap. 79). The ethanol flushing response may involve prostaglandin and histamine release. Both prostaglandin antagonists (aspirin)¹⁸⁹ and antihistamines (H₁ and H₂)^{129,178,185} may attenuate this response.

CYP2E1 is responsible for very little ethanol metabolism in the non tolerant drinker, but becomes more important as the ethanol concentration rises or as ethanol use becomes chronic (Fig. 80–1). CYP2E1 uses reduced nicotinamide adenine dinucleotide phosphate (NADPH) as an electron donor in a complex process that ultimately oxidizes ethanol to acetaldehyde.¹⁰⁴ In this process, hydrogen is abstracted from ethanol and donated to molecular oxygen to form water. Subsequently, acetaldehyde is further oxidized to acetate as hydrogen ion is transferred from acetaldehyde to NADP⁺. The ability of ethanol to induce the CYP2E1 forms the basis for the well-established interactions between ethanol and a host of other xenobiotics metabolized by this system.^{41,57} In alcoholics and those with higher ethanol concentrations, cimetidine may also delay ethanol clearance by inhibiting CYP2E1.⁷² However, the increase in blood ethanol concentration from such an interaction is of questionable clinical significance.^{5,6,22,23}

ADH is saturated at relatively low blood ethanol concentrations. As the system is saturated, ethanol elimination changes from first-order to zero-order kinetics (Chap. 9). In adults, the average rate of ethanol metabolism is 100 to 125 mg/kg/h in occasional drinkers and up to 175 mg/kg/h in habitual drinkers.^{18,67} As a result, the average-sized adult metabolizes 7 to 10 g/h and the blood ethanol concentration falls 15 to 20 mg/dL/h (3.26–4.35 mmol/L/h). Tolerant drinkers, by recruiting CYP2E1, may increase their clearance of ethanol to 30 mg/dL/h (6.52 mmol/L/h) or even higher.^{18,67} Studies of ethanol-intoxicated patients indicate that although the average ethanol clearance rate is about 20 mg/dL/h (4.35 mmol/L/h), there is considerable individual variation (standard deviation of about 6 mg/dL/h (1.30 mmol/L/h)).^{18,67}

XENOBIOTIC INTERACTIONS

Ethanol interacts with a variety of xenobiotics (Table 80–2).^{92,196} The most frequent ethanol–drug interactions occur as a result of ethanol-induced increase in hepatic xenobiotic-metabolizing enzyme activity. In contrast, acute ethanol use may inhibit metabolism of other xenobiotics, and this may be due to competitive inhibition of hepatic enzyme activity or a reduction in hepatic blood flow. The interaction between ethanol and disulfiram (Antabuse) is well described, and it can be life threatening (Chap. 79).

TABLE 80–2. Ethanol Xenobiotic Interactions

<i>Xenobiotics</i>	<i>Adverse Effects</i>
Antihistamines (H ₁)	Additive sedative effect
Aspirin	Enhance antiplatelet effect
Carbamates	Disulfiramlike effect
Cephalosporins ^a	Disulfiramlike effect
Chloral hydrate	Additive sedative effect
Chloramphenicol	Disulfiramlike effect
Chlorpropamide	Disulfiramlike effect
<i>Coprinus</i> spp mushrooms	Disulfiramlike effect
Cyclic antidepressants	Additive sedative effect
Disulfiram (Antabuse)	Nausea, vomiting, abdominal pain, flushing, diaphoresis, chest pain, headache, vertigo, palpitations
Griseofulvin	Disulfiramlike effect
Isoniazid	Increased incidence of hepatitis; increased metabolism ^b
Methadone	Increased methadone metabolism ^b
Metronidazole	Disulfiramlike effect
Nitrofurantoin	Disulfiramlike effect
Opioids	Additive sedative effect
Oral hypoglycemics	Potentiates hypoglycemic effect
Phenothiazines	Additive sedative effect
Phenytoin	Increased phenytoin metabolism ^b
Ranitidine, cimetidine	Increased ethanol concentration
Sedative-hypnotics	Additive sedative effect/respiratory depression
Thiram derivatives	Disulfiramlike effect
Vasodilators	Potentiates vasodilator effect
Warfarin	Increased warfarin metabolism ^b

^aThose containing a *N*-methylthiotetrazole side chain. ^bEffect possibly associated with chronic alcohol consumption.

Concomitant use of cocaine and ethanol leads to the formation of an active metabolite, cocaethylene, through transesterification of cocaine by the liver.¹⁵⁶ Cocaethylene has a longer half-life than cocaine itself (2 hours vs. 48 minutes), and this may explain some of the delayed cardiovascular effects attributed to cocaine use.^{8,203} Both ethanol and cocaethylene inhibit the metabolism of cocaine, thereby prolonging the elimination of cocaine and enhancing its effect (Chap. 78).¹⁴⁷

Case reports and retrospective case series that suggest chronic ethanol consumption may predispose a person to acetaminophen (APAP) hepatotoxicity (Chap. 35),^{47,118,125,167,211} even when APAP has been taken according to the manufacturer's recommended dosage of not more than 4 g daily.²¹² Because ethanol induces CYP2E1, the enzyme involved in the metabolism of APAP to its hepatotoxic intermediate, N-acetyl-p-benzoquinone imine, a theoretical basis for this association exists. However, in randomized, placebo-controlled trials where confirmed alcoholics were given APAP 4 g

daily or placebo, there were no differences between the two groups with regard to liver enzymes or to their coagulation profile.¹⁶³ Recent fasting, common in alcoholics, was also associated with a predisposition to APAP hepatotoxicity, likely due to depletion of glutathione (Chap. 35).²⁰⁰ However, in a retrospective study, heavy drinkers did not develop more severe hepatotoxicity following APAP overdose than nondrinkers.¹¹⁹

PATHOPHYSIOLOGY

Despite the long history of ethanol use and study, no specific receptor for ethanol has been identified, and the mechanism of action leading to intoxication remains the subject of debate.¹⁵¹ Ethanol is known to affect a large number of membrane proteins that participate in signaling pathways such as neurotransmitter receptors, enzymes, and ion channels,^{136,194} and there is extensive evidence that ethanol interacts with a variety of neurotransmitters.^{50,190,191} The major actions of ethanol involve enhancing the inhibitory effects of γ -aminobutyric acid (GABA) at GABA_A receptors and blockade of the N-methyl-d-aspartate (NMDA) subtype of glutamate, an excitatory amino acid (EAA) receptor.^{37,102,103,194} Animal studies indicate that the acute effects of ethanol result from competitive inhibition of glycine binding to the NMDA receptor and disruption of glutamatergic neurotransmission by inhibiting the response of the NMDA receptor. Persistent glycine antagonism and attenuation of glutamatergic neurotransmission by chronic ethanol exposure results in tolerance to ethanol by enhancing EAA neurotransmission and NMDA receptor upregulation.^{85,135,187,190,191} The latter appears to involve selective increases in NMDA R2B subunit concentrations and other molecular changes in specific brain loci.⁴ The abrupt withdrawal of ethanol thus produces a hyperexcitable state that leads to the ethanol withdrawal syndrome and excitotoxic neuronal death.^{16,37,190} GABA-mediated inhibition, which normally acts to limit excitation, is eliminated during the ethanol withdrawal syndrome and further intensifies this excitation. In addition, NMDA receptors function to inhibit the release of dopamine in the nucleus accumbens and mesolimbic structures, which modulates the reinforcing action of addictive xenobiotics such as ethanol.^{20,21,177} By inhibiting NMDA receptor activity, ethanol could increase dopamine release from the nucleus accumbens and ventral tegmental area and could thus create dependence. Chronic ethanol administration also results in tolerance, dependence, and an ethanol withdrawal syndrome, mediated, in part, by desensitization and or downregulation of GABA_A receptors (Chaps. 14, 15, and 81).

Chronic alcoholism has multiorgan system effects (Table 80–3), and the relationships between ethanol use, nutrition, and liver disease have been reviewed elsewhere.¹¹⁴ In addition to the harmful effects of ethanol itself such as impairment of protein synthesis, its metabolite, acetaldehyde, is inherently toxic to biologic systems.^{108,112,193,210} Acetaldehyde directly impairs cardiac contractile function, disrupts cardiac excitation-contraction coupling, inhibits myocardial protein synthesis, interferes with phosphorylation, causes structural and functional alterations in mitochondria and hepatocytes, and inactivates acetyl-CoA. Acetaldehyde can also react with intracellular proteins to generate adducts. Acetaldehyde-protein and DNA adducts promote oxidative stress, lipid peroxidation, hepatic stellate cells activation-associated inflammation and fibrosis, and mutagenesis. Acetaldehyde adducts are believed to be important in the early phase of alcoholic liver disease, and in advanced liver disease they contribute to the development of hepatic fibrosis as well as hepatocellular carcinoma.¹⁷¹

TABLE 80–3. Systemic Effects Associated with Alcoholism

Cardiovascular	Esophagus	Genitourinary	Intoxication
Cardiomyopathy	Boerhaave syndrome	Hypogonadism	Korsakoff psychosis
"Holiday heart" (dysrhythmias)	Cancer of the esophagus	Impotence	Marchiafava-Bignami disease
"Wet" beriberi (thiamine deficiency)	Diffuse esophageal spasm	Infertility	Myopathy
Endocrine and metabolic	Esophagitis	Hematologic	Pellagra
Hypoglycemia	Mallory-Weiss tear	Coagulopathy	Polyneuropathy
Hypokalemia	Stomach and duodenum	Folate, B ₁₂ , iron-deficiency anemias	Wernicke encephalopathy
Hypomagnesemia	Gastritis	Hemolysis (Zieve syndrome, stomatocytosis, spur-cell anemia)	Ophthalmic
Hypophosphatemia	Chronic hypertrophic gastritis	Leukopenia	Tobacco-ethanol amblyopia
Hypothermia	Diarrhea	Thrombocytopenia	Psychiatric
Hypertriglyceridemia	Hematemesis	Neurologic	Animated behavior
Hyperuricemia	Malabsorption	Alcohol amnesic syndrome	Loss of self-restraint
Metabolic acidosis	Peptic ulcer	Alcoholic hallucinosis	Manic-depressive illness
Malnutrition	Liver	Alcohol withdrawal	Suicide and depression
Gastrointestinal	Cirrhosis	Central pontine myelinolysis	Respiratory
Mouth	Hepatitis	Cerebral atrophy (dementia)	Atelectasis
Cancer of the mouth, pharynx, larynx	Steatosis	Cerebellar degeneration	Pneumonia
Cheliosis	Pancreas	Cerebrovascular accident (subarachnoid hemorrhage, infarction)	Respiratory depression
Nutritional stomatitis	Pancreatitis (acute or chronic)		Respiratory acidosis

Ethanol metabolism through the CYP2E1 pathway generates highly reactive oxygen radicals, including the hydroxyethyl radical molecule. Elevated oxygen radical concentrations generate a state of oxidative stress, which leads to cell damage. Oxygen radicals can also initiate lipid peroxidation resulting in reactive molecules such as malondialdehyde and 4-hydroxy-2-nonenal. These reactive molecules react with proteins or acetaldehyde to form adducts, which contribute to the development of alcoholic liver injury.³⁸

Oxidation of ethanol generates an excess of reducing potential in the cytosol in the form of NADH with the ratio of NADH to NAD⁺ being dramatically increased. This ratio, also known as the redox potential, determines the ability of the cell to carry on various oxidative processes. The unfavorable change in redox potential due to ethanol metabolism contributes to the development of metabolic disorders, such as impaired gluconeogenesis, alterations in fatty acid metabolism, fatty liver, hyperlipidemia, hypoglycemia, elevated lactate concentration, hyperuricemia (gouty attacks), increased collagen and scar tissue formation associated with alcoholism, and a clinical syndrome of alcoholic ketoacidosis (AKA).

Studies in alcoholic liver disease have focused on Kupffer cell activation by endotoxin that is released by intestinal bacteria. When Kupffer cells are activated, they produce regulatory nuclear factor kappa β (NF κ B) and generate significant amounts of superoxide radicals (O₂⁻) and cytokines (tumor necrosis factor and interleukin-8), which is an essential factor in the injury to hepatocytes associated with alcoholic liver disease.^{124,199}

ACUTE CLINICAL FEATURES

Ethanol is a selective central nervous system (CNS) depressant at low doses and a general depressant at high doses. Initially it depresses those areas of the brain involved with highly integrated functions. Cortical release leads to animated behavior and the loss of restraint. This paradoxical CNS stimulation is due to disinhibition. In cases of mild intoxication, the signs of ethanol inebriation are quite variable. The patient may be energized and loquacious, expansive, emotionally labile, increasingly gregarious or may appear to have lost self-control, exhibit antisocial behavior, and be ill tempered. As the degree of intoxication increases, there is successive inhibition and impairment of neuronal activity. The patient may become irritable, abusive, aggressive, violent, dysarthric, confused, disoriented, or lethargic. With severe intoxication, there is loss of airway protective reflexes, coma, and increasing risk of death from respiratory depression. An ethanol-naive adult with a blood ethanol concentration of greater than 250 mg/dL (54 mmol/L) is usually comatose.¹

However, the acute effects of ethanol ingestion also depend on the habituation of the drinker. This is mainly due to the development of tolerance, which has both a metabolic (pharmacokinetic) and a functional (pharmacodynamic) component.¹⁸¹ Metabolic tolerance to ethanol is based on enhanced elimination by ADH, and to a greater extent, CYP2E1. Functional tolerance (resistance to the effects of ethanol at the cellular level) is a more important determinant of habituation and is mediated through alterations in GABA_A and NMDA receptors as well as serotonergic (eg, 5-HT_{1A}) and adrenergic

neurons.^{85,97,98,135,180–191} Acute ethanol tolerance is demonstrated by the Mellanby effect, which involves the comparison of physiologic responses or behavioral effects at the same blood ethanol concentration on the ascending and descending limbs of the blood ethanol concentration–versus–time curve. Impairment is greater at a given blood ethanol concentration when it is increasing than for the same blood ethanol concentration when it is falling.^{139,195} Although individuals who are acutely intoxicated move through a progressive sequence of events, the association of a particular aspect of intoxication with a specific blood ethanol concentration is not usually possible without knowing the pattern of ethanol use of the patient. Acute ethanol intoxication occurs in habitual drinkers when they raise their ethanol concentration an equivalent amount above baseline, and specific clinical manifestations of inebriation typically occur with significantly higher blood ethanol concentration than in nontolerant individuals. Regardless, the absolute change above baseline may be important.

A patient may present with obvious signs and symptoms consistent with ethanol intoxication that include flushed facies, diaphoresis, tachycardia, hypotension, hypothermia, hypoventilation, mydriasis, nystagmus, vomiting, dysarthria, muscular incoordination, ataxia, altered consciousness, and coma. However, an ethanol-intoxicated patient may present to the emergency department (ED) with a broad range of diagnostic possibilities and should prompt a careful evaluation for a variety of covert clinical and metabolic disorders. A meticulous and systematic approach to the evaluation and management of an inebriated patient will help avoid the potential pitfalls in such a situation.⁶¹ The presence or absence of an odor of ethanol on the breath is an unreliable means of ascertaining if a person is intoxicated or if ethanol was recently consumed.¹³⁴ Diplopia, visual disturbances, and nystagmus may be evident, which may be due to the toxic effects of ethanol or may represent Wernicke encephalopathy. Hypothermia may be exacerbated by environmental exposure, from malnutrition and loss of carbohydrate or energy substrate, and from ethanol-induced vasodilation. Ethanol intoxication can impair cardiac output in patients with preexisting cardiac disease⁶⁹ and induce dysrhythmias such as atrial fibrillation, atrioventricular block, and nonsustained ventricular tachycardia.^{45,70,71} The association between ethanol use and cardiac dysrhythmias, particularly supraventricular tachydysrhythmias, in apparently healthy people is called “holiday heart syndrome.”^{99,105,127} The syndrome was first described in people with heavy ethanol consumption, who typically presented on weekends or after holidays, and it may also occur in patients who binge but who usually drink little ethanol. The most common dysrhythmia is atrial fibrillation, which usually reverts to normal sinus rhythm within 24 hours. Although the syndrome may recur, the clinical course is benign in patients without anatomic cardiac pathology and specific antidysrhythmic therapy is usually not warranted.^{59,71} Acute heavy ethanol drinking may precipitate silent myocardial ischemia in patients with stable angina pectoris.¹⁶² Variant angina is reported to occur in patients following ethanol ingestion at a time when the blood ethanol concentration has decreased to almost zero.^{53,91,122,130,145,165,184} Ethanol-induced seizures are reported in adults but are more frequent in children with ethanol-induced hypoglycemia.^{31,84} Patients presenting with acute ethanol intoxication commonly have decreased serum ionized magnesium concentrations, while their total serum magnesium concentration is within the normal range.²⁰⁸ However, total body magnesium may be depleted due to poor dietary intake, decreased GI absorption secondary to ethanol, and renal wasting due to the ethanol-related diuresis.^{54,90,159,172,179}

DIAGNOSTIC TESTS

There are numerous qualitative and quantitative assays for ethanol in biological fluids and exhaled breath. Immunoassay or gas chromatography is commonly used for determination of ethanol in liquid specimens in most hospitals. Hospital laboratory analysis of blood samples for ethanol content is usually based upon serum (liquid portion of whole blood after the cellular components and clotting factors have been removed), or rarely plasma (acellular liquid portion of whole blood). In contrast, forensic casework expresses ethanol concentration in terms of ethanol concentration in whole blood (Special Considerations: SC6).

Ethanol saliva testing is a promising alternative to breath ethanol analysis in the rapid assessment of blood ethanol concentrations in patients regardless of their mental status.^{35,175} Fatty acid ethyl esters (FAEEs) may be a highly sensitive test for recent ethanol use.^{14,43,176} Because FAEEs remain in the body for at least 24 hours, they may have a role as a marker of recent ethanol use even after ethanol is completely metabolized. However, their availability is limited, and their place in patient management is undefined.

Ethyl glucuronide and ethyl sulfate are nonoxidative direct ethanol metabolites and are excreted for considerably longer time than ethanol.^{17,32,75,164,168} Testing for these metabolites in urine has gained popularity as a sensitive method to detect recent ethanol intake and is favored over tests such as γ -glutamyl transferase or carbohydrate-deficient transferrin, particularly by agencies concerned with monitoring an individual for recent ethanol consumption or relapse; confirming abstinence in treatment programs, workplaces, and schools; and providing legal proof of drinking.^{74,154} The presence of ethyl glucuronide and ethyl sulfate provides a strong indication of recent drinking even when ethanol is no longer detectable.⁷⁵ However, caution should be applied in the interpretation of ethyl glucuronide testing results. Ethyl glucuronide may be sensitive to degradation or may be synthesized by bacteria (eg, *Escherichia coli*) such that infected urine may result in either a false negative or false positive test, particularly when specimens have been improperly stored; ethyl sulfate

degradation or formation has not been detected under similar conditions.^{78,79} Detection windows for ethyl glucuronide and ethyl sulfate after drinking may be limited and dependent on the amount of ethanol consumed. For example, these metabolites are detectable in urine for ≤ 24 hours after intake of 0.25 g/kg ethanol and ≤ 48 hours after intake of 0.50 g/kg ethanol.^{32,73,75,81,82,206} Depending on the analytical cutoff limit, unintentional exposure to ethanol-based mouthwash and hand sanitizers may result in a urine positive for ethyl glucuronide or ethyl sulfate.^{29,161} There appears to be a marked interindividual variation in the concentration-time profiles for both metabolites. In situations where the times for ethanol intake and urine specimen collection between drinking and sampling are uncertain, it is not possible to link a single ethyl glucuronide and sulfate result to a specific ethanol dose taken at a specific time.⁷⁷ A common cutoff or reporting limit is yet to be determined for urinary ethyl glucuronide and ethyl sulfate when used as ethanol biomarkers.

Laboratory investigations that should be considered for patients with ethanol intoxication include a rapid reagent glucose test, complete blood count, electrolytes, blood urea nitrogen, creatinine, ketones, acetone, lipase, liver enzymes, ammonia, calcium, and magnesium. Patients with an anion gap metabolic acidosis should have urine ketones and a serum lactate concentration determined (Chaps. 19 and 109). High serum acetone concentrations may be indicative of isopropanol intoxication, whereas elevated serum or urinary ketones may be indicative of AKA, starvation ketosis, or diabetic ketoacidosis (DKA). Because the laboratory nitroprusside reaction detects only ketones (acetoacetate and acetone) and not β -hydroxybutyrate, the assay for urinary ketones may be only mildly positive in patients with AKA.

A blood ethanol concentration should be included in the initial laboratory studies.⁸³ If the blood ethanol concentration is inconsistent with the clinical condition of the patient, prompt reevaluation is indicated to elucidate the etiology of the altered mental status including toxic-metabolic (eg, hypoglycemia, electrolyte or acid-base disorder, toxic alcohols, therapeutic or illicit drug overdose, ethanol withdrawal, hepatic encephalopathy, and Wernicke-Korsakoff syndrome), trauma-related, neurologic (eg, postictal condition), and infectious etiologies. Comatose patients with concentrations below 300 mg/dL (65 mmol/L) and those with values in excess of 300 mg/dL (65 mmol/L) who fail to improve clinically during a limited period of close observation should have a head computed tomography (CT) scan, followed by a lumbar puncture if warranted. Because chronically ethanol-tolerant patients are prone to trauma and coagulopathies, both of which can cause intracerebral bleeding, the threshold for head CT scanning should be low.

MANAGEMENT OF THE INTOXICATED PATIENT

Ethanol is rapidly absorbed from the GI tract. In situations where recent ingestion (within one hour of presentation), delayed absorption, and concomitant ingestions are under consideration, GI decontamination may be considered. Occasionally, the extremely intoxicated or comatose patient may have severe respiratory depression necessitating endotracheal intubation and ventilatory support.

Any patient with an acute altered mental status mandates immediate investigation and treatment of reversible etiologies such as hypoxia, hypoglycemia, and opioid toxicity. In addition, Wernicke encephalopathy should be considered. Supplemental oxygen should be administered if the patient is hypoxic, and intravenous dextrose (0.5–1.0 g/kg), thiamine 100 mg, and naloxone 0.4 mg should be administered as clinically indicated. Abnormal vital signs should be addressed and stabilized. Patients who are combative and violent should be both physically and then chemically restrained. Randomized clinical trials suggest both benzodiazepine (ie, midazolam) and antipsychotics (ie, droperidol) are effective as “chemical restraints” in the ED setting.^{86,100,121,140} Midazolam has a more rapid onset of action and has a shorter duration of effect compared with droperidol.^{86,100,121,140} Patients receiving midazolam required more additional sedation and required airway management compared with patients receiving droperidol.^{86,100,121} Although the efficacy of midazolam and droperidol has been confirmed by multiple studies,^{86,100,121,140} they were not designed to inform about safety, equivalence, or superiority of midazolam and droperidol. Caution should be taken because of additive effects of ethanol and benzodiazepine on respiratory depression. Attempts by those who are significantly clinically intoxicated to sign out against medical advice or attempt to leave should also be prevented (Chap. 141). The fluid and electrolyte status of the patient should be assessed and abnormalities corrected. Multivitamins with folate, thiamine, and magnesium may be added to the maintenance intravenous solution.

A variety of therapies have been advocated either to reverse the intoxicating effects of ethanol or to enhance its elimination. Those proven to be either ineffective or unreliable include coffee, caffeine, naloxone, flumazenil, and rapid intravenous saline loading.^{55,111,142,143,160} Hemodialysis is an effective means of enhancing the systemic elimination of ethanol because of the small volume of distribution and low molecular weight of ethanol. In severe ethanol poisoning resulting in respiratory failure or coma, hemodialysis may be an adjunct treatment to supportive care. However, the risks and benefits of hemodialysis should be considered.

INDICATIONS FOR HOSPITALIZATION

A patient with uncomplicated ethanol intoxication can be safely discharged after a careful observation with social service

or psychiatric counseling. An individual should not be discharged while still clinically intoxicated. However, consideration may be given to a situation where the intoxicated patient is discharged to a protected environment under the supervision of a responsible not intoxicated adult. In all cases except allowing a person to drive, the clinical assessment of the patient is more important than the blood ethanol concentration. Indications for hospital admission include persistently abnormal vital signs, persistently abnormal mental status with or without an obvious cause, an overdose with intended self-harm, concomitant serious trauma, consequential ethanol withdrawal, and an associated serious disease process such as pancreatitis or GI hemorrhage.

Chronic alcoholism leads to an organic brain syndrome that is irreversible. The socioeconomic condition of the patient and the ability to comply with a treatment plan are critical in making a disposition. Alcoholics requesting ethanol detoxification can be admitted for rehabilitation. Inpatient detoxification programs differ substantially from outpatient programs, but their most consequential advantages may be that they enforce abstinence, provide more support and structure, and separate the patient from the social surroundings associated with drinking.¹³⁸ For patients who are not admitted, a referral should be offered to Alcoholics Anonymous or another suitable ethanol rehabilitation program.

ETHANOL-ASSOCIATED HYPOGLYCEMIA

Hypoglycemia associated with ethanol consumption occurs when ethanol metabolism increases the cellular redox ratio. The higher redox state favors the conversion of pyruvate to lactate, diverting pyruvate from gluconeogenesis (Fig. 80–2). Hypoglycemia typically occurs when there is a reduced caloric intake and only after the hepatic glycogen stores are depleted, as in an overnight fast. The mechanism by which hypoglycemia is associated with ethanol consumption in the well nourished individual is less well defined.

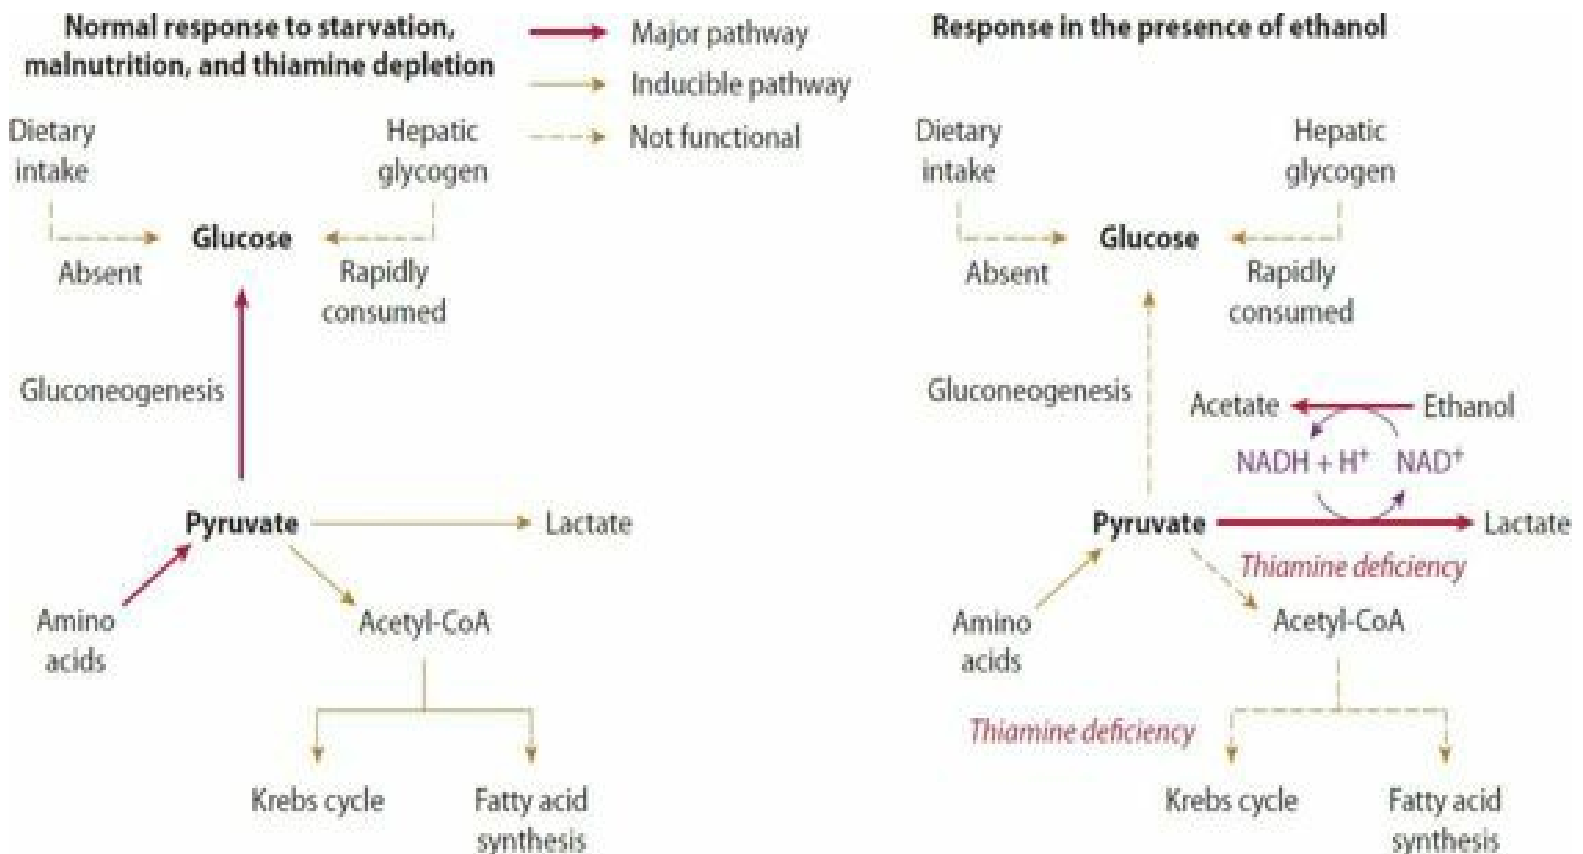

FIGURE 80–2 Central role of pyruvate in ethanol-induced hypoglycemia. Thiamine deficiency interrupts metabolism at the indicated steps.

Although the conditions associated with hypoglycemia in adults may also be present in infants and children, children, with their smaller liver, have less glycogen stores than adults and are more likely to develop hypoglycemia. Hypoglycemia associated with ethanol consumption usually occurs in malnourished chronic alcoholics and children. It may also occur in binge drinkers who do not eat. A 22% incidence of hypoglycemia was reported in one retrospective study of children with documented ethanol ingestion.¹⁰⁹ In another retrospective study of children and adolescents, there was a 3.4% incidence of hypoglycemia (serum glucose concentration less than 67 mg/dL {3.7 mmol/L})⁴⁹; children younger than 5 years of age have an increased risk of developing hypoglycemia, and it is the most common reported clinical abnormality related to ethanol ingestion in this age group.^{106,107}

Clinical Features

Patients with ethanol-associated hypoglycemia usually present with an altered consciousness 2 to 10 hours following ethanol ingestion. Other physical findings include hypothermia and tachypnea. Laboratory findings, in addition to hypoglycemia, usually include a positive blood ethanol concentration, ketonuria without glucosuria, and mild acidosis.

Management

Acute treatment of ethanol-associated hypoglycemia is similar to other causes of hypoglycemia ([Chap. 53](#) and Antidotes in Depth: A12) and should prompt a systematic evaluation for coexisting clinical and metabolic disorders. Hospital admission is indicated as this represents serious metabolic impairment.

ALCOHOLIC KETOACIDOSIS

The development of AKA requires that a combination of physical and physiologic events occur. The normal response to starvation and depletion of hepatic glycogen stores is for amino acids to be converted to pyruvate. Pyruvate can serve as a substrate for gluconeogenesis, be converted to acetyl-CoA, which can enter the Krebs cycle or can be utilized in various biosynthetic pathways (eg, fatty acids, ketone bodies, cholesterol, and acetylcholine). As described earlier, ethanol metabolism generates NADH, resulting in an excess of reducing potential. This high redox state favors the conversion of pyruvate to lactate, diverting pyruvate from being a substrate for gluconeogenesis. To compensate for the lack of normal metabolic substrates, the body mobilizes fat from adipose tissue and increases fatty acid metabolism as an alternative source of energy. This response is mediated by a decrease in insulin and an increased secretion of glucagon, catecholamines, growth hormone, and cortisol. Fatty acid metabolism results in the formation of acetyl-CoA, and it combines with the excess acetate that is generated from ethanol metabolism to form acetoacetate ([Fig. 80–3](#)).⁶⁰ Most of the acetoacetate is reduced to β -hydroxybutyrate due to the excess reducing potential or high redox state of the cell. Volume depletion interferes with the renal elimination of acetoacetate and β -hydroxybutyrate and contributes to the acidosis. An elevated lactate concentration may result from shunting from pyruvate or from hypoperfusion or infection that may coexist with the underlying ketoacidosis.

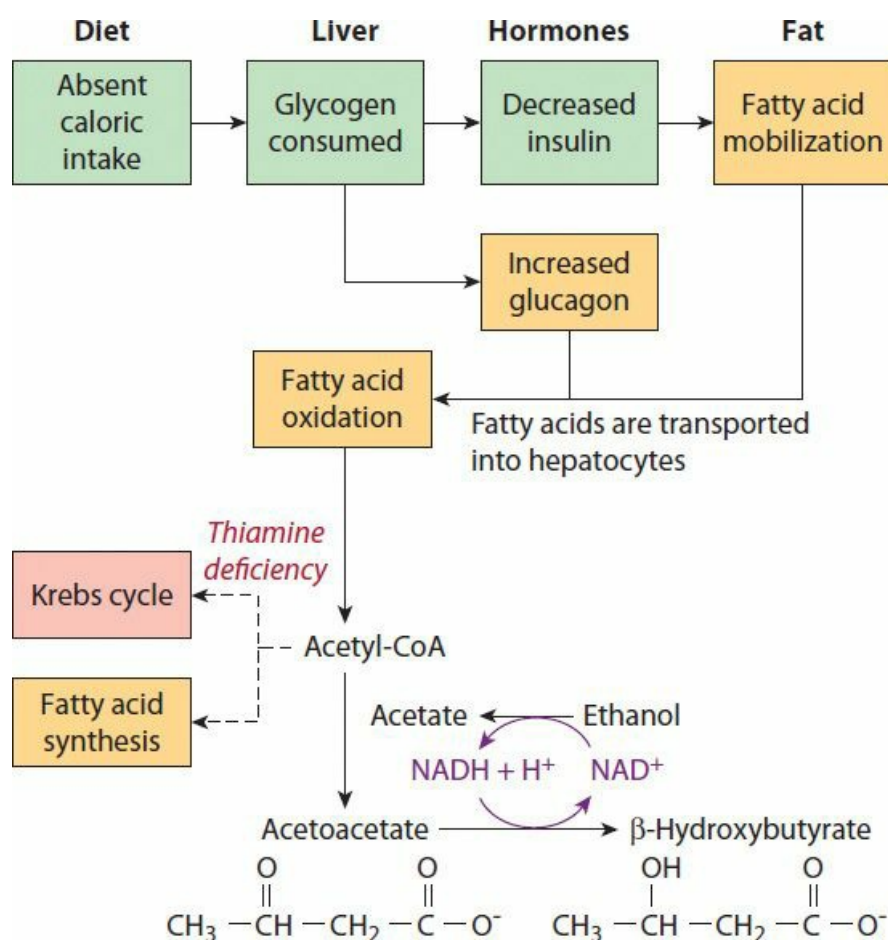

FIGURE 80–3 Mechanism of alcoholic ketoacidosis. Thiamine deficiency interrupts metabolism at the indicated steps.

Clinical Features

Patients with AKA are typically chronic ethanol users, presenting after a few days of “binge” drinking, who become acutely

starved because of cessation in oral intake due to bingeing itself or to nausea, vomiting, abdominal pain from gastritis, hepatitis, pancreatitis, or a concurrent acute illness.^{61–63} The patient may appear acutely ill with salt and water depletion, tachypnea, tachycardia, and hypotension. Underlying medical conditions such as sepsis, meningitis, pyelonephritis, or pneumonia may be present, and ethanol withdrawal may develop, all of which should be considered and systematically excluded. The diagnosis of AKA is a diagnosis of exclusion.

The blood ethanol concentration is usually low or undetectable because ethanol intake ceased substantially earlier in the clinical course. The hallmarks of AKA include an elevated anion gap metabolic acidosis with an elevated serum lactate concentration insufficient to account for the gap. However, some patients will have a normal blood pH or may be even alkalemic because of an associated primary metabolic alkalosis due to vomiting and a compensatory respiratory alkalosis (Chap. 19).⁶⁰ When patients with AKA are compared with patients with DKA, those with AKA tended to have a higher blood pH, lower serum potassium and chloride concentrations, and a higher serum bicarbonate concentration.⁶⁴ The etiology of anion gaps in patients with AKA and DKA is very similar, with β -hydroxybutyrate being the primary anion contributor and lactate having a less consequential role.⁶⁴

The nitroprusside test used to detect the presence of ketones in serum and urine may be negative or mildly positive in patients with AKA because the nitroprusside reaction detects only molecules containing ketone moieties. This includes acetone and acetoacetate but not β -hydroxybutyrate. Reliance on the nitroprusside test alone may underestimate the severity of ketoacidosis. Specific assays for β -hydroxybutyrate may be performed in some hospital laboratories and may be available as point-of-care testing at the bedside. The blood glucose may be low or mildly elevated. It is postulated that ethanol-induced hypoglycemia occurs first, causing increased levels of cortisol, growth hormone, glucagon, and epinephrine; this may correct the hypoglycemia and mobilize fatty acids, which are converted to ketones.³⁶ Therefore, alcoholic hypoglycemia and AKA may be sequential events of the same process, depending on the point in this process at which the patient is evaluated.

Management

Treatment should begin with adequate crystalloid fluid replacement, dextrose, thiamine, and folic acid. Supplemental multivitamins, potassium, and magnesium should be instituted on an individual basis. The administration of dextrose will stimulate the release of insulin, decrease the release of glucagon, and reduce the oxidation of fatty acids. Exogenous glucose also facilitates the synthesis of adenosine triphosphate (ATP), which reverses the pyruvate-to-lactate and NAD^+ -to-NADH ratios. The provision of thiamine facilitates pyruvate entry into the Krebs cycle, thus increasing ATP production. Volume replacement restores glomerular flow and improves excretion of ketones and organic acids. Administration of either insulin or sodium bicarbonate in the management of AKA is usually unnecessary.⁶³

During the recovery phase of AKA, β -hydroxybutyrate is converted to acetoacetate. As this process occurs, the nitroprusside test may become more positive because of higher concentrations of acetoacetate, resulting in hyperketonemia and ketonuria, which represents improvement of the metabolic status.

Patients presenting with AKA are manifesting serious metabolic impairment and require hospital admission. They may succumb to other precipitating or coexisting medical or surgical disorders⁶¹ such as occult trauma, pancreatitis, GI hemorrhage or hepatorenal dysfunction, and infections. However, mortality is rare from ethanol-induced ketoacidosis.

ALCOHOLISM

Alcoholism is traditionally defined as a chronic, progressive disease characterized by tolerance and physical dependence to ethanol and pathologic organ changes. Alcoholism is a multifactorial, genetically influenced disorder.^{30,80,138,150,157,170,186}

Screening is a preliminary procedure to assess the likelihood that an individual has a substance use disorder or is at risk of negative consequences from alcohol or other xenobiotics use. Whereas screening tools such as the Brief Michigan Alcoholism Screening Test (MAST)¹⁵³ and the CAGE questions¹²³ (Tables 80–4 and 80–5) were initially developed to identify people with active alcohol dependence for referral to treatment, the screening, brief intervention, and referral to treatment (SBIRT) was developed as a public health model designed to provide universal screening, secondary prevention in detecting risky or hazardous substance use before the onset of abuse or dependence, early intervention, and treatment for people who have problematic or hazardous alcohol problems within health care settings.⁷ Based on the Substance Abuse and Mental Health Services Administration (SAMHSA) model, SBIRT allows for universal screening of all patients regardless of an identified disorder, allowing health care professionals to address the spectrum of such behavioral health problems even when the patient is not actively seeking intervention or treatment.

TABLE 80–4. The Brief Michigan Alcoholism Screening Test

Question	Circle Correct Answer		Points
1. Do you feel you are a normal drinker?	Yes	No	N2
2. Do friends or relatives think you are a normal drinker?	Yes	No	N2
3. Have you ever attended a meeting of Alcoholics Anonymous?	Yes	No	Y5
4. Have you ever lost friends or girlfriends/boyfriends because of drinking?	Yes	No	Y2
5. Have you ever gotten into trouble at work because of drinking?	Yes	No	Y2
6. Have you ever neglected your obligations, your family, or your work for 2 or more days in a row because you were drinking?	Yes	No	Y2
7. Have you ever had delirium tremens (DTs) or severe shaking, or heard voices, or seen things that weren't there after heavy drinking?	Yes	No	Y2
8. Have you ever gone to anyone for help about your drinking?	Yes	No	Y5
9. Have you ever been in a hospital because of drinking?	Yes	No	Y5
10. Have you ever been arrested for drunk driving after drinking?	Yes	No	Y2
Score 6 = Probable diagnosis of alcoholism.			

Adapted with permission, from Pokorny AO, Miller BA, Kaplan HB: *Am J Psychiatry*. 1972;129:342–345. Copyright 1972, American Psychiatric Association.

TABLE 80–5. The CAGE Questions

1. Have you ever felt you should cut down on your drinking?
2. Have people annoyed you by criticizing your drinking?
3. Have you ever felt bad or guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye-opener)?

Two or more affirmatives = probable diagnosis of alcoholism.

Data from Mayfield D, McLeod G, Hall P: The CAGE questionnaire: validation of a new alcoholism screening instrument. *Am J Psychiatry*. 974;131:1121–1126.

The presence of tolerance and or dependence is not essential for a diagnosis of alcoholism. Emphasis instead is placed on the social and behavioral concomitants of heavy drinking.¹³³ In the ED setting, questions concerning the ability of the patient to function physically and psychologically are just as appropriate as quantifying the amount of ethanol consumed per day.

Alcoholism is commonly associated with affective disorders, especially depression.^{131,155} There is a higher rate of alcoholism among patients with bipolar disorder than in the general population, and there may be a genetic relationship between alcoholism and depression.^{95,144,204,205} Ethanol affects mood, judgment, and self-control; creates a clinical condition conducive to violence directed at self and others; and is an important risk factor for suicide. Although many people drink in an attempt to ameliorate their depression, all available evidence suggests that alcoholism adversely affects mood and cognitive ability. Research indicates alcoholism may be partly under genetic control.^{10,95,101,115} Chromosomal linkage analysis has implicated chromosomes 9, 15, and 16 in the genetic predisposition to alcoholism.^{13,39,117} Polymorphism in ADH and ALDH genes appears to be a marker for risk of alcoholism.^{27,30,48,186,188} The ADH1B*2, ADH1C*1, and ALDH2*2 alleles are associated with reduced risk of alcoholism. Genetic epidemiologic studies strongly correlate Asians with homozygous ADH1B*2 and ALDH2*2 alleles with reduced ethanol consumption and incidence of alcoholism.^{30,150,202} The incidence of both homozygous ADH1B*1 and ALDH2*1 alleles was significantly higher in patients with ethanol dependence and in patients with alcoholic liver disease.

Various strategies are employed to treat alcoholism, including psychosocial interventions, pharmacological interventions, or both. Pharmacologic treatment of ethanol dependence that is of potential collateral toxicologic

consequence include opioid antagonists naltrexone, acamprosate, disulfiram, serotonergic agents, and topiramate.^{65,87}

Although alcoholism is a serious disease with important health and economic consequences, it continues to be underdiagnosed and remains a treatment challenge.^{120,207}

SUMMARY

- Ethanol is widely used in society, and ethanol use problems impose a staggering personal, social, and economic burden on society.
- Domestic violence, child abuse, fires, falls, sexual assault, and other crimes such as robbery and assault, as well as medical consequences such as cancer, liver disease, and heart disease have all been associated with ethanol misuse.
- Ethanol research suggests that genetics may be an important determinant in vulnerability to ethanol dependence.
- Acute ethanol intoxication and alcoholism are among the most common and complex toxicologic and societal problems.
- Patients with acute ethanol intoxication or alcoholism may present with a diversity of clinical problems that challenge the clinician to be meticulous and systematic in the evaluation and management of these patients.

A24 ANTIDOTES IN DEPTH

Thiamine Hydrochloride

Robert S. Hoffman

INTRODUCTION

Thiamine (vitamin B₁) is a water-soluble vitamin found in organ meats, yeast, eggs, and green leafy vegetables that is essential in the creation and utilization of cellular energy. While there is no toxicity associated with thiamine excess, thiamine deficiency is responsible for “wet” beriberi (congestive heart failure) and “dry” beriberi (Wernicke encephalopathy and the Wernicke-Korsakoff syndrome). Patients at risk include those with poor oral intake (HIV-AIDS, cancer, fad diets, anorexia nervosa, bulimia, hyperemesis gravidarum, and following bariatric surgery), those with impaired absorption (alcoholism and bariatric surgery), and those with enhanced elimination (high dose loop diuretic therapy). Typical signs of Wernicke encephalopathy include ataxia, altered mental status, and ophthalmoplegia. Although administration of 100 mg of parenteral thiamine hydrochloride will protect against thiamine deficiency for more than one week, patients with clinical deficiencies may require larger doses for a longer period of time.

HISTORY

Kanehiro Takaki, a physician in the Japanese navy, first established the relationship between a nutritional deficiency and beriberi in 1884. It was not until 1901 that Gerrit Grijns determined that the nutrient, as yet unnamed, was contained in the outer coat of rice and was lost during the polishing process. Ten years later, Casimir Funk isolated thiamine, and Williams finally determined its structure in 1934. Originally thiamine was called aneurin for “antineuritic vitamin”¹⁹ and was ultimately synthesized by Cline, Williams, and Finkelstein.²⁵ In 1936, Peters demonstrated that thiamine could reverse neurologic disease in nutritionally deprived pigeons and that improvement was coupled to an enhanced ability to metabolize pyruvate.⁸²

In 1881, Carl Wernicke reported three alcoholic patients who died after developing confusion, ataxia, and ophthalmoplegia.¹¹⁷ Autopsies showed characteristic hemorrhages surrounding the third and fourth ventricles. A few years later, Sergei Korsakoff reported amnesia and confabulation in 30 alcoholics that was preceded in many by the clinical findings reported by Wernicke.¹²⁵ Today, these two neurologic disorders are often combined and called the Wernicke-Korsakoff syndrome in recognition that they are likely a spectrum of the same disease.

PHARMACOLOGY

Biochemistry

As a coenzyme in the pyruvate dehydrogenase complex, thiamine diphosphate (thiamine pyrophosphate), the active form of thiamine, facilitates the conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). This reaction occurs at the C2 atom of thiamine, which is located between the nitrogen and sulfur atoms on the thiazolium ring.³⁸ In the protein-rich environment of the enzyme complex, this C2 atom is deprotonated to form a carbanion that rapidly attaches to the carbonyl group of

pyruvate, thereby stabilizing it for decarboxylation.⁵⁴ In a series of subsequent reactions, the hydroxyethyl group that remains bound to thiamine diphosphate is transferred to lipoamide, where an acetyl group is later broken off and attached to coenzyme A (CoA). This overall process links anaerobic glycolysis to the Krebs cycle, where subsequent aerobic metabolism produces the equivalent of 36 moles of adenosine triphosphate (ATP) from each mole of glucose (Fig. A24-1). When pyruvate cannot be converted to acetyl-CoA because of thiamine deficiency, for example, only two moles of ATP can be generated by anaerobic metabolism from each mole of glucose. Within the Krebs cycle, thiamine is also required as a cofactor for the α -ketoglutarate dehydrogenase complex to catalyze the reaction of α -ketoglutarate to succinyl-CoA (Fig. A24-2), and for transketolase, an enzyme in the pentose phosphate pathway, in which nicotinamide adenine dinucleotide phosphate (NADPH) is formed for subsequent use in reductive biosynthesis.^{12,136} In addition to its metabolic effects, thiamine also has a role as a neuromodulator, influencing acetylcholine release.⁴⁸

FIGURE A24-1 Thiamine links anaerobic glycolysis to the Krebs cycle. Anaerobic glycolysis only yields two moles of ATP as each mole of glucose is metabolized to two moles of pyruvate. To obtain the 34 additional ATP equivalents that can be derived as the Krebs cycle converts pyruvate to CO₂ and H₂O, pyruvate must first be combined with CoA to form acetyl-CoA and CO₂. This process is dependent on the thiamine-requiring enzyme system known as pyruvate dehydrogenase complex.

FIGURE A24-2. Thiamine is essential for α -ketoglutarate dehydrogenase activity, which is a rate-limiting step within the Krebs cycle. Thiamine deficiency leads to an accumulation of α -ketoglutarate, which is shunted to glutamate and causes excitatory neurotoxicity.

Naturally occurring thiamine is a base composed of a substituted pyrimidine ring and a substituted thiazole ring connected by a methylene bridge. This connection between the two rings is weak, and the molecule is unstable in an alkaline milieu and in a high temperature environment. In addition, thiamine is highly water soluble, allowing it to leach out of foods following prolonged washing or cooking in water. However, thiamine, which is synthesized as a hydrochloride salt, is usually quite stable. Thiamine requirements are determined by total caloric intake and energy demand, with 0.33 mg of thiamine required for every 4400 kJ (1000 kcal) of energy.¹⁰³ The recommended daily consumption is 0.5 mg/1000 kcal in order to provide a margin of safety.¹⁰²

Pharmacokinetics

Thiamine is well absorbed from the human gastrointestinal tract by a complex process.^{62,88} At low concentrations, thiamine absorption occurs through a saturable mechanism that is most effective in the duodenum, with absorption occurring to a lesser degree in the large bowel and stomach.⁶² As thiamine concentrations increase, however, the majority of absorption occurs through simple passive diffusion. A placebo-controlled human volunteer study evaluated the kinetics of oral administration of 100, 500, and 1500 mg in healthy subjects.¹⁰³ Following the 100 mg dose, peak concentrations occurred in whole blood in 3.43 hours. Although higher doses produced higher peak concentrations with a delay in time, the lack of linearity of the dose-response relationship confirmed complex absorption kinetics.¹⁰³ Synthesized analogs such as thiamine propyl disulfide, benfotiamine, and fursultiamine have enhanced bioavailability, but their use remains largely experimental.^{38,119} Chronic liver disease, folate deficiency, steatorrhea, and other forms of malabsorption all significantly decrease the absorption of thiamine.^{26,104} Recently, bariatric surgery was recognized to predispose patients to thiamine deficiency.^{1,3,34,96,97} Malabsorption has even greater clinical relevance in alcoholics.^{7,116} In experimental studies, when healthy volunteers were given small amounts of ethanol, a 50% reduction in gastrointestinal thiamine absorption resulted.¹¹⁶ A rat model confirmed that the simple presence of ethanol in the gut impairs thiamine absorption rather than the effects of chronic ethanol use alone.⁴⁹

Two genes are involved in the cellular transport of thiamine: a high affinity thiamine transporter known as THTR1 (SLC19A2) and a low affinity thiamine transporter known as THTR2 (SLC19A3).^{39,40} Variations or mutations in these genes may predispose to thiamine deficiency and cause thiamine-responsive megaloblastic anemia syndrome. Homozygous or compound heterozygous mutations in THTR2 can manifest two distinct clinical phenotypes, biotin-responsive basal ganglia disease and Wernicke-like encephalopathy.¹³⁴ Experimental evidence suggests that ethanol intake directly alters gene transcription, further increasing risk.¹²⁰ These models demonstrate ethanol-induced reductions in the expression of

intestinal thiamine transporters at the protein, mRNA, and transcriptional (promoter activity) levels.¹¹⁰

Thiamine is eliminated from the body largely by renal clearance, which consists of a combination of glomerular filtration, flow-dependent tubular secretion, and saturable tubular reabsorption.¹²⁹ In an animal model, furosemide, acetazolamide, chlorothiazide, amiloride, mannitol, and salt loading all significantly increased urinary elimination of thiamine.⁶⁹ This nonspecific flow-dependent elimination was confirmed in humans given small doses of furosemide.⁸⁷ Interestingly spironolactone use is associated with higher thiamine concentrations.⁸⁹ Additionally, both furosemide and digoxin appear to inhibit thiamine uptake into myocardial cells.¹³⁵

THIAMINE DEFICIENCY

Pathophysiology

Mice develop signs of encephalopathy 10 days after being rendered thiamine deficient. Immunohistochemistry in these animals demonstrates destruction of the blood–brain barrier with resultant extravasation of albumin.⁴³ Similarly, rats develop symptoms after 10 days of thiamine deficiency and subsequently demonstrate deterioration of the blood–brain barrier with hemorrhage into the mammillary bodies and other areas of the brain.¹⁷ This pattern is similar to findings described in humans with Wernicke encephalopathy.⁸⁴ Although there are no controlled trials of thiamine deprivation in humans, several unfortunate events support this time course. One report describes three patients who were given total parenteral nutrition without multivitamins; signs and symptoms developed in 7, 10, and 14 days, respectively.¹²⁴ Similar reports confirm this time course with some variability based on the nutritional status of the patients.^{4,61,74,80} Infants given a soy-based formula that lacked thiamine also developed findings consistent with Wernicke encephalopathy.³²

The proximate cause of Wernicke encephalopathy is unclear. In human autopsy studies, brain samples from alcoholic patients with Wernicke-Korsakoff syndrome demonstrate decreased function of pyruvate dehydrogenase, α -ketoglutarate dehydrogenase, and transketolase when compared with controls.¹⁵ However, a similar decrease in enzyme activity of neuronal tissue was demonstrated in alcoholics who died from hepatic coma without ever manifesting signs of Wernicke encephalopathy.⁶⁵ This finding is understandable given that high concentrations of ammonia inhibit α -ketoglutarate dehydrogenase.¹² Likewise, the activity of thiamine-requiring Krebs cycle enzymes is reduced in thiamine-replete patients with neurodegenerative diseases.¹¹ Thus, while thiamine deficiency produces deficits in critical enzymes in humans, many have argued that it is unclear whether these deficits are either necessary or sufficient to produce clinical disease.

Animal models offer insight into the mechanisms involved in developing thiamine-deficient neurologic injury. While the exact chain of events leading to these structural abnormalities is unclear, several models demonstrate key portions of the pathway. Thiamine deficiency in rats produces 200% to 640% increases in concentrations of glutamate,⁶⁴ which presumably results from blockade of α -ketoglutarate dehydrogenase. Excess α -ketoglutarate is shunted away from the Krebs cycle to form glutamate. Rats subsequently develop increases in lactate in vulnerable regions of the brain marked by the induction of the protooncogene c-fos. Both the histochemical lesions and the gene induction can be blocked by the administration of the calcium channel blocker nicardipine.⁷³ This suggests a strong role for excitatory amino acid–induced alterations in calcium transport in the genesis of thiamine-deficient encephalopathy.⁵² In other animal models of thiamine deficiency, neuronal tissues are also directly injured by oxidative stress and lipid peroxidation.^{18,45,46,52} Additional investigations demonstrate roles for triggered mast cell degranulation,³³ histamine,⁶⁴ and nitric oxide⁵⁸ in the generation of neuronal injury. The final common pathway is localized cerebral edema, which may result from altered expression of aquaporin.²³

In what may be the most important finding since Wernicke's original description, is that Kono and colleagues recently described two healthy nonalcoholic brothers who developed signs, symptoms, and neuroimaging findings consistent with Wernicke encephalopathy despite normal serum thiamine concentrations.⁵⁷ Both brothers were confirmed to have compound mutations of the SLC19A3 gene (K44E and E320Q) encoding for low-affinity thiamine transport (THTR2). High-dose thiamine (up to 600 mg) was clinically effective. The more severe E320Q homozygous THTR2 mutation manifests as impaired thiamine uptake, progressive brain atrophy, bilateral thalamic and basal ganglia lesions, and epileptic spasms beginning early in infancy.¹³⁴ Several other mutations (including G23V and T422A and those inducing premature termination codons) produce loss of thiamine THTR2 transport function and a spectrum of generalized dystonia; epilepsy; and bilateral striatal, caudate, putamen, and cortical lesions.^{27,99,109} Patients may respond to high-dose thiamine and/or biotin.⁹⁹ As demonstrated by magnetic resonance imaging, vasogenic edema is a characteristic finding during the acute crises.¹¹² When added to the cases where thiamine was excluded from total parenteral nutrition or infant formula, these findings definitively relate intracellular thiamine concentrations to clinical and anatomical manifestations of Wernicke encephalopathy and thiamine deficiency.

Clinical Manifestations

When thiamine is completely removed from the human diet, tachycardia is often the first sign of deficiency. The clinical symptoms of thiamine deficiency present as two distinct patterns: “wet” beriberi or cardiovascular disease and “dry” beriberi, the neurologic disease known as Wernicke-Korsakoff syndrome. Although some patients display symptoms consistent with both disorders, usually either the cardiovascular or the neurologic manifestations predominate. A genetic variant of transketolase activity, combined with low physical activity and low-carbohydrate diet, may predispose to neurologic symptoms, whereas high-carbohydrate diets and increased physical activity lead to cardiovascular symptoms.^{10,131} Thus, cardiovascular disease is more common in the Asian population, and neurologic disease predominates in the northern European population.

Wet beriberi results from high output cardiac failure induced by peripheral vasodilation and the formation of arteriovenous fistulae secondary to thiamine deficiency. These patients complain of fatigue, decreased exercise tolerance, shortness of breath, and peripheral edema. Myocardial edema may be demonstrated.³¹ The classic triad of oculomotor abnormalities, ataxia, and global confusion defines dry beriberi or Wernicke encephalopathy. Other manifestations include hypothermia and the absence of deep-tendon reflexes.¹²⁸ Vomiting and anorexia are common^{32,124} and may be related to increases in intracranial pressure. Additionally, patients develop a peripheral neuropathy with paresthesias, hypesthesias, and an associated myopathy, all related to axonal degeneration.¹⁰² Laboratory studies may reflect a metabolic acidosis with elevated lactate concentration brought on by excessive anaerobic glycolysis resulting from blocked entry of substrate into the Krebs cycle.^{22,24,55,56,63,81,90,128} Interestingly, a primary respiratory alkalosis of unclear etiology seems to be simultaneously present.²⁹ Korsakoff psychosis, an irreversible disorder of learning and processing of new information characterized by a deficit in short-term memory and confabulation, often occurs together with Wernicke encephalopathy.¹²⁵ A 10% to 20% mortality rate is associated with Wernicke encephalopathy, with survivors having an 80% risk of developing Korsakoff psychosis.⁸⁶

A clinical tool for identifying patients with Wernicke encephalopathy used four signs: dietary deficiencies, oculomotor abnormalities, cerebellar dysfunction, and either an altered mental status or mild memory impairment. When two or more signs were present the tool was highly sensitive and specific.¹⁶

Epidemiology: Populations at Risk

In the United States, a healthy diet and mandatory thiamine supplementation of numerous food products protect most people from the manifestations of thiamine deficiency. Despite this, the prevalence of Wernicke encephalopathy in the general US population is estimated to be between 0.2% and 2.2%, although only 20% of these cases are estimated to be diagnosed during their lifetime.^{68,108} This is, unfortunately, not true in other countries. A survey of the 17 major public hospitals in the Sydney, Australia, area identified more than 1000 cases of either acute Wernicke encephalopathy or Korsakoff psychosis between 1978 and 1993.⁷⁰ Similarly, a single Australian hospital identified 32 cases of Wernicke encephalopathy during a 33-month period.¹³² In Australia, mandatory supplementation of flour with thiamine in 1991 resulted in a dramatic reduction in hospitalized cases during 1992 and 1993,⁷⁰ as well as of the percentage of cases diagnosed by postmortem studies.⁴⁴ Other countries at risk include Ireland and New Zealand, where lack of a mandatory thiamine supplementation program is correlated with a high prevalence of biochemical evidence of thiamine deficiency.⁷⁸

Alcoholic patients, whose consumption of ethanol is their major source of calories, are the best described and most easily recognized patients at risk for thiamine deficiency.⁸⁶ In Scotland, 21% of alcoholics requiring emergency admission to the hospital were thiamine deficient, as determined by erythrocyte transketolase.⁵⁰ The prevalence in US alcoholics is estimated to be 12.5%.¹⁰⁸

Consequential thiamine deficiency is also described in incarcerated prisoners,⁵¹ patients in drug rehabilitation,³⁵ patients receiving hemodialysis,²⁸ patients with hyperemesis gravidarum or anorexia nervosa,¹¹⁵ patients receiving parenteral nutrition,^{4,20,21,24,61,63,80,81,111,124,126} patients with acquired immunodeficiency syndrome (AIDS),^{5,13,14,95} patients with malignancies,^{9,59,91,123} the institutionalized elderly,^{60,77–79} critically ill children,^{53,66} patients with sepsis,²⁹ patients with congestive heart failure on furosemide therapy,⁶⁰ patients with malabsorption secondary to *Clostridium difficile* diarrhea,²⁶ patients with eating disorders,¹²⁷ and most recently, patients who had undergone bariatric surgery.^{1,3,34,37,96} Thus, despite routine dietary supplementation, many people are still at risk because of dietary limitations, alcohol abuse, or underlying medical or surgical conditions.

ROLE IN PREVENTION AND TREATMENT OF WERNICKE ENCEPHALOPATHY

Thiamine hydrochloride is included in the initial therapy for any patient with an altered mental status, potentially acting as

both treatment and prevention of Wernicke encephalopathy. Many patients with altered levels of consciousness have had or will have a poor nutritional status or will be hospitalized and deprived of oral intake for a number of days because of gastrointestinal disorders or altered mental status. Although thiamine concentrations can be either directly measured or functionally assessed by measuring erythrocyte transketolase activity at baseline and in response to thiamine diphosphate administration,⁴⁷ these determinations are unavailable for clinical use and do not correlate with disease severity.⁶⁸ Likewise, although clinical prediction models have been developed, they are cumbersome and unvalidated.¹⁰⁰ Glucose loading increases thiamine requirements, which can exacerbate marginal thiamine deficiencies, elevate lactate concentrations,⁷⁶ or even precipitate coma in the absence of parenteral thiamine supplementation.⁸⁶ Although it is commonly believed that acute glucose loading, in the form of a bolus of hypertonic dextrose, can precipitate Wernicke encephalopathy over several hours in normal individuals, there is evidence to support this effect only in patients who already have grave manifestations of thiamine deficiency or exaggerated delay in the provision of thiamine.^{71,92,128} Previously healthy patients require prolonged dextrose administration in the absence of thiamine in order to develop Wernicke encephalopathy. Because the morbidity and mortality associated with Wernicke encephalopathy are so severe and underdiagnosed, and treatment is both benign and inexpensive, thiamine hydrochloride should be included in the initial therapy for all patients who receive dextrose, all patients with altered consciousness, and every potential alcoholic or nutritionally deprived individual who presents to the emergency department or other clinical setting.

ROLE IN THE TREATMENT OF OTHER DISORDERS
